Virions are composed of about 15–25 percent lipids, their composition reflecting that of the region of the host cell membrane where virions bud. Generally, phospholipids represent about 55–60 percent, and sterols and glycolipids about 35–40 percent of the total lipids. Virions are composed of about 3 percent carbohydrates by weight, which are present as *N*- and *O*-linked glycan chains on surface proteins and on glycolipids. When made in mammalian cells the oligosaccharide chains are generally of the complex type, in insect cells they are of noncomplex types.

In the *Filoviridae*, *Paramyxoviridae*, and *Rhabdoviridae*, discrete mRNAs are transcribed by sequential interrupted synthesis. Transcription is polar with stepwise attenuation. Generally genes do not overlap, the exceptions being the *M2* and *L* genes of respiratory syncytial virus (family *Paramyxoviridae*, subfamily *Pneumovirinae*, genus *Pneumovirus*), the *VP30* and *VP24* genes of *Lake Victoria marburgvirus* (family *Filoviridae* genus *Marburgvirus*) and the *VP35/VP40*, *GP/VP30*, and *VP24/L* genes of *Zaire ebolavirus* (family *Filoviridae*, genus *Ebolavirus*). The site of multiplication is the cytoplasm, with the exception of plant viruses classified in the genus *Nucleorhabdovirus*. The *P* genes of respiroviruses and morbilliviruses are exceptional in that additional open reading frames may be utilized via alternative non-AUG start codons, and mRNA editing occurs by insertion of nontemplated nucleotides to change the reading frame for the expression of *P* gene products. In the filovirus *Zaire ebolavirus*, a nontemplated insertion event during transcription of the glycoprotein gene generates the membrane-inserted glycoprotein seen in virions, whereas the faithfully transcribed mRNA encodes a secreted form of the glycoprotein lacking the membrane anchor. This does not appear to occur in the other filovirus, *Lake Victoria marburgvirus*. In the *Bornaviridae*, the site of multiplication is the nucleus and transcription is complex with splicing of mRNA and overlapping transcriptional stop/start signals.

Replication occurs by synthesis of a complete positive sense anti-genomic RNA. Genomic and anti-genomic RNAs are present only as nucleocapsids. The mRNAs of bornaviruses are capped, but synthesis is not inhibited by α-amanitin suggesting that a cap-snatching mechanism is not involved. In the filoviruses, paramyxoviruses and rhabdoviruses, maturation of the independently assembled helical nucleocapsid occurs by budding through host membranes with investment by a host-derived lipid envelope containing transmembrane proteins. The process of assembly and maturation of bornaviruses is not understood at present.

Membrane glycoproteins are involved in antibody-mediated neutralisation. Virus serotypes are defined by the surface antigens. Filoviruses are an exception in that they are poorly neutralized in vitro. In bornaviruses antibodies to both the glycosylated matrix protein and the gp94 envelope protein neutralize infectivity.

The host ranges vary from restricted to unrestricted. Filoviruses have only been isolated from primates. Paramyxoviruses occur only in vertebrates and no vectors are known. Rhabdoviruses infect invertebrates, vertebrates, and plants. Some rhabdoviruses multiply in both invertebrates and vertebrates, some in invertebrates and plants, but none in all three. In human hosts the pathogenic potential tends to be characteristic of the family: i.e. hemorrhagic fever (*Filoviridae*); respiratory and neurological diseases (*Paramyxoviridae*); mild febrile to fatal neurological diseases (*Rhabdoviridae*). Bornaviruses have been isolated from horses, cattle, sheep, rabbits, rats, cats, ostriches, and man. The pathology associated with virus infection is variable. Infection of animals is associated with conditions ranging from behavioral disturbances to severe nonpurulent encephalomyelitis, and there is some evidence of association of bornavirus

infection with neuropsychiatric illness in man. Cytopathology varies from none (bornaviruses and filoviruses) to rapidly lytic (rhabdoviruses and paramyxoviruses); syncytium formation is common in paramyxoviruses.

BRIEF DESCRIPTIONS OF THE FOUR FAMILIES COMPRISING THE ORDER *MONONEGAVIRALES*

The family *Bornaviridae*

The family *Bornaviridae* is represented by *Borna disease virus*, a species of some antiquity. Borna disease takes its name from the town of Borna in Saxony, Germany, where extensive outbreaks of fatal neurological disease in horses, and occasionally sheep, have occurred at least since 1895. The viral etiology of the disease was established in 1925, but it was not recognized to be a negative-sense RNA virus until 1995. As yet, no other virus with comparable molecular characteristics has been isolated. Borna disease was considered to be sporadically endemic only in Central Europe, but it may have spread worldwide in recent times. In horses, the outcome of infection is often death, and surviving animals may exhibit permanent sensory or motor deficiencies. No data are available that might identify reservoir hosts facilitating the spread of the virus, and there is no evidence for vectorborne transmission. The question of the involvement of Borna disease virus in human neuropsychiatric illness remains unresolved, but experimental infection of a primate (the tree shrew *Tupaia*) appeared to induce aberrant social behaviour and altered response to environmental stimuli (see also: Borna disease virus).

The family *Filoviridae*

The family *Filoviridae* comprises two genera, *Ebolavirus* and *Marburgvirus. Marburgvirus* is represented by a single species, now designated *Lake Victoria marburgvirus*, whereas *Ebolavirus* is represented by four distinct species *Cote d'Ivoire ebolavirus*, *Reston ebolavirus*, *Sudan ebolavirus*, and *Zaire ebolavirus*. All these viruses, except for *Reston ebolavirus*, which does not appear to be pathogenic for humans, have been associated with outbreaks of acute and often fatal hemorrhagic fever in Central Africa. The virions exhibit similar filamentous pleomorphic morphology and virus infectivity is poorly neutralized in vitro. There is virtually no cross-reactivity between the two genera. The amino acid homology of the surface glycoproteins of ebolaviruses and marburgviruses is approximately 30 per cent, compared with 55–66 percent between ebolavirus species. The natural reservoirs of filoviruses are unknown, but no vector appears to be involved in transmission (see also: Filoviruses).

The family *Paramyxoviridae* – subfamily *Paramyxovirinae*

The family *Paramyxoviridae* is divided into two subfamilies; the *Paramyxovirinae* containing the five genera *Avulavirus, Henipavirus, Morbillivirus, Respirovirus*, and *Rubulavirus*; and the *Pneumovirinae* containing the two genera *Pneumovirus* and *Metapneumovirus*. The features exhibited by all members of the *Paramyxovirinae* are the following: identical genome organisation consisting of six (seven in some rubulaviruses) transcriptional elements; nucleocapsid diameter of 18 nm, 5.5 nm pitch; genome length a multiple of six nucleotides; a 3' leader of approximately 55 nucleotides with the first three nucleotides (ACC) absolutely conserved; conserved transcription start and stop signals; RNA editing site in the *P/V* gene; fusion and attachment functions segregated to separate glycoproteins (F and HN or H) that exhibit sequence relatedness across the subfamily.

The avian pathogen *Newcastle disease virus* was long regarded as representative of all paramyxoviruses, but as molecular characterization of other paramyxoviruses progressed it became apparent that *Newcastle disease virus* possessed unique properties. Consequently, it has been reassigned as the sole member of the new genus *Avulavirus* and it is anticipated that other avian paramyxoviruses may be reassigned to this genus when more molecular information is available. The genus *Respirovirus* comprises *Sendai virus*, *Human parainfluenza viruses 1* and *3*, *Bovine parainfluenza virus 3*, and *Simian virus 10*. The genus *Morbillivirus* comprises *Measles virus*, *Canine distemper virus*, *Rinderpest virus*, and *Peste-des-petits-ruminants virus*. In addition, *Cetacean morbillivirus* and *Phocine distemper virus*, two viruses from marine mammals, have been added to the *Morbillivirus* genus recently. The genus *Rubulavirus* comprises *Mumps virus*, *Human parainfluenza viruses 2* and *4*, *Porcine rubulavirus*, *Simian virus 5*, *Simian virus 41*, and three viruses isolated from bats – *Mapuera virus*, Menangle virus, and Tioman virus. The avian paramyxoviruses are currently grouped with the rubulaviruses but this is expected to alter with the advent of molecular characterization of these viruses. Recently two other viruses isolated from bats in South-east Asia and Australia – Hendra virus and Nipah virus – proved to be related to each other but quite distinct from the bat rubulaviruses and indeed other paramyxoviruses. As a consequence these viruses have been assigned to a new genus *Henipavirus*. These viruses are distinguished by their larger genome size (18 kb compared with the uniform 15–16 kb of all other paramyxoviruses). The size of the *Henipavirus* gene products is similar to those of other viruses in the subfamily, with the exception of

the P protein which is approximately 100 amino acids longer than the longest P protein previously characterized. The size, sequence, and domain structure of the Hendra virus L protein are very similar to those of other viruses in the subfamily. Extensive phylogenetic analyses of both full-length L protein and the more conserved domain III sequences confirmed that Hendra virus is a member of the subfamily *Paramyxovirinae* and is more closely related to morbilliviruses and respiroviruses (see below and Figure 1a). However, the L proteins of the two henipaviruses and Tupaia paramyxovirus (an as yet unclassified paramyxovirus isolated from the tree shrew *Tupaia belangeri* in Thailand) differ from the L proteins of other negative-sense RNA viruses in one important respect. The four-amino acid sequence GDNQ, that is absolutely conserved among all known *L* genes of negative-sense RNA viruses is replaced by GDNE (Figure 1b). This sequence resides in the highly conserved and functionally important C motif of domain III of all negative-sense RNA virus polymerases.

The subfamily *Paramyxovirinae* is an ever-expanding taxonomic group; Salem virus, isolated in North America from a horse, and Tupaia paramyxovirus are in the process of characterization and their place in the

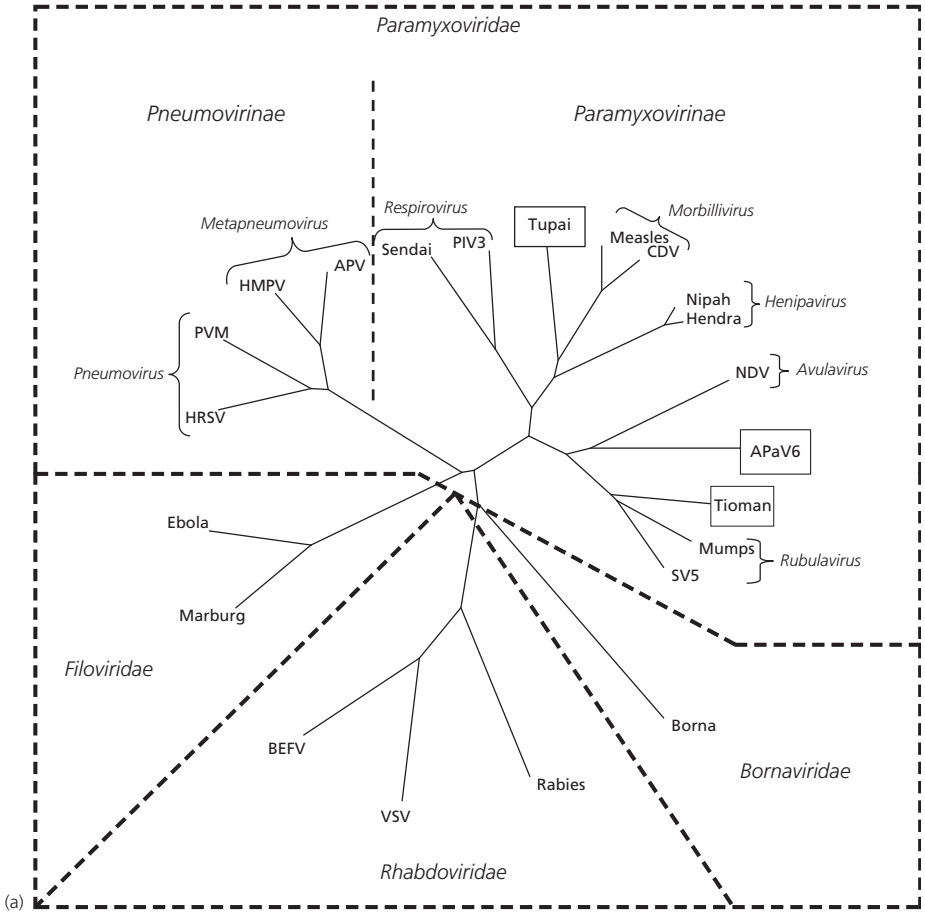

Figure 1 (a) *Unrooted phylogenetic tree of members of the order* Mononegavirales*. The tree was constructed using the CLUSTALX programme with the sequences of the conserved domain III region of the* L *polymerase proteins (Poch et al. 1989, 1990). The ICTV classification designations of the viruses are indicated. For the* Paramyxoviridae*, the two subfamilies and five genera are also indicated. The unclassified Tupaia paramyxovirus (Tupai), avian parainfluenzavirus type 6 (ApaV6) and Tioman virus (Tioman) are indicated.* **(b)** *Alignment of the domain III region sequences of members of the order* Mononegavirales*. The four conserved polymerase motifs (A–D) are indicated. The conserved GDNQ motif is highlighted. The viruses are:* Sendai virus *(Sendai; Middleton et al. 1990),* human parainfluenza virus type 3 *(HPIV-3; Galinski et al. 1988), Tupai paramyxovirus (Tupai; Accession number NP_054697), Measles virus (measles; Bankamp et al. 1999), Canine distemper virus (CDV; Sidhu et al. 1993), Nipah virus (Nipah; Chan et al. 2001), Hendra virus (Hendra; Wang et al. 2000), Newcastle disease virus (NDV; Yusoff et al. 1987), avian paramyxovirus 6 (ApaV6; Accession number NP_150063), Tioman virus (Tioman; Chua et al. 2002), Mumps virus (Mumps; Okazaki et al. 1992), Simian virus 5 (SV5; Higuchi et al. 1992), Human respiratory syncytial virus (HRSV; Tolley et al. 1996), pneumonia virus of mice (PVM; L. Thorpe and A. Easton, unpublished), Human metapneumovirus (HMPV; Accession number AF371337), avian pneumovirus (APV; Randhawa et al. 1996), Marburg virus (Marburg; Muhlberger et al. 1992), Ebola virus, strain Zaire (Ebola; Volchkov et al. 2000), Rabies virus (Rabies; Conzelmann et al. 1990), Vesicular stomatitis Indiana virus (VSV; Schubert et al. 1984), Bovine ephemeral fever virus (BEFV; Walker et al. 1994), Borna disease virus (Borna; Briese et al. 1994). existing taxonomy is still uncertain. Paramyxoviruses have been isolated frequently from reptiles, including snakes, lizards, and turtles. Preliminary molecular characterization of 18 reptilian viruses, isolated from 18 species of snakes belonging to three different families, suggests that these viruses should be classified in a new genus within the subfamily *Paramyxovirinae* (Franke et al. 2001) .

The family *Paramyxoviridae* – subfamily *Pneumovirinae*

Members of this subfamily are distinguished by the possession of 8 or 10 transcriptional elements, smaller open reading frames, an additional unglycosylated nucleocapsid-associated M2 (sometimes designated 22k) protein, an extensively *O*-linked G (attachment) protein, an unedited *P* gene and in some members, two 3′-terminal nonstructural protein genes (*NS1* and *NS2*). The open reading frames encode proteins with little amino acid sequence homology with those of any of the *Paramyxovirinae* except in the *F* and *L* genes. The nucleocapsid diameter is 13–14 nm and the pitch is 7 nm. The G protein is structurally unrelated to the HN or H proteins of the *Paramyxovirinae* and exhibits a high level of strain variability with as little as 53 percent identity between strains.

The subfamily *Pneumovirinae* comprises two genera: *Pneumovirus* and *Metapneumovirus*. The genus *Pneumovirus* includes three virus species: *Human respiratory syncytial virus*, *Bovine respiratory syncytial virus*, and *Pneumonia virus of mice*. The bovine and human respiratory syncytial viruses share considerable sequence and antigenic relatedness, with the F and HN proteins exhibiting 81 percent identity. They differ predominantly in their hosts. Murine pneumonia virus (sometimes still given as Pneumonia virus of mice) differs from the other two species to a greater extent, with amino acid sequence relationships varying from almost nil in the case of the NS1 and NS2 proteins to 60 percent identity in the case of the nucleoprotein (NP). Pneumonia virus of mice lacks the *M2/L* gene overlap present in the genome of human respiratory syncytial virus and the pneumonia virus of mice *P* gene encodes several additional proteins by using alternative AUG translation initiation codons. Gene transfer experiments have established that the functions of the proteins encoded by the 3′-terminal *NS1* and *NS2* genes, which have no homologues in other paramyxoviruses, are involved in suppression of the antiviral interferon response of infected cells.

The second genus *Metapneumovirus* was originally assigned to accommodate the avian virus *Turkey rhinotracheitis virus* (also known as avian pneumovirus), and has recently been extended by the inclusion of a human virus (designated provisionally as human metapneumovirus), which closely resembles its avian counterpart in molecular properties, but exists in the same biological niche as human respiratory syncytial virus. The metapneumoviruses lack the 3′-terminal *NS1* and *NS2* genes characteristic of other pneumoviruses and exhibit a displacement of the *SH-G* and *F-M2* gene pairs in the gene order. This is rather remarkable since the same relative gene order is conserved throughout the order *Mononegavirales*, except for the two virus species making up the genus *Metapneumovirus* and some genetically engineered recombinant rhabdoviruses (see below). All of the pneumoviruses lack a neuraminidase and all, except pneumonia virus of mice, a hemagglutinating activity. In contrast to the *Paramyxovirinae*, in none of the known pneumoviruses is the genome size a multiple of six nucleotides (see also: Pneumovirus and metapneumovirus).

The family *Rhabdoviridae*

The rhabdoviruses infecting vertebrates are bullet-shaped or cone-shaped, whereas the rhabdoviruses infecting plants appear bacilliform when fixed prior to negative staining or bullet-shaped or pleomorphic if unfixed. The virions are 100–430 nm long and 45–100 nm in diameter. The nucleocapsid of rhabdoviruses contains RNA polymerase activity and is infectious, whereas the naked negative-sense RNA genome is not. Some putative plant viruses, identified solely by electron microscopy appear to lack envelopes. The family consists of six genera: *Vesiculovirus, Lyssavirus, Ephemerovirus, Novirhabdovirus, Cytorhabdovirus*, and *Nucleorhabdovirus*. The genomic RNA has a 5′-terminal phosphate and is not polyadenylated. The ends of the genome have inverted complementary sequences, a feature consistent with the mechanism of replication of rhabdoviruses. Defective RNAs are easily detected because the size of the encapsidated RNA determines the linear dimension of the virus particle. Defective RNAs are dependent on infectious virus but they also interfere specifically with replication, and are responsible for reduction of virus yields by autointerference in virus passaged at high multiplicity.

Currently, nine species and at least 19 tentative species have been assigned to the genus *Vesiculovirus*. These viruses originate from mammals, fish and insects. *Vesicular stomatitis Indiana virus* is the type species of the genus and represents the basic organisational pattern for the entire order *Mononegavirales*. The 11.2 kb genome encodes a 3′-leader sequence of 47 nucleotides that precedes the N, P, M, G, and L open reading frames, which are separated by minimal intergenic dinucleotides, and terminates in a 54 nucleotide trailer region. There is a common 3′-AUACUUUUUUU sequence preceding each intergenic region and a UUGUCNNU sequence at the beginning of each gene.

The leader region is transcribed and a Le RNA may be present in the nuclei of infected cells. The viruses in this genus show varying degrees of amino acid identity in N protein comparisons. *Vesicular stomatitis Indiana virus* has been employed widely as a model system in virus research since all the gene products are structural proteins and can be isolated from purified virions. The genus *Lyssavirus* contains *Rabies virus* and another six rabies-related viruses, four of which originate from bats. Until recently the island continent of Australia was considered to be rabies-free prior to the isolation of *Australian bat lyssavirus* from both pteropid and insectivorous bats. Phylogenetic analysis of the genomes of these viruses suggest that they may have been endemic in Australia prior to European colonization. The 11.9 kb rabies virus genome comprises a 60 nucleotide leader region followed by the five basic rhabdovirus genes, separated by di- or pentanucleotides and followed by a 70 nucleotide trailer. (Exceptionally, the Pasteur strain includes a 423 nucleotide pseudogene region between the *G* and *L* genes which is transcribed within the G mRNA). The rabies viruses are neurotropic and all the viruses in the genus show some antigenic cross-reactivity. The viruses classified in the genus *Ephemerovirus* depart significantly from the standard rhabdovirus pattern. There are three species in the genus: *Bovine ephemeral fever virus*, *Adelaide river virus*, and *Berrimah virus*. The 14.9-kb genome of *Bovine ephemeral fever virus* encodes ten genes in the order 3′-N–P–M–G–Gns–α1–α2–β–γ–L-5′, with intergenic regions of between 26 and 53 nucleotides. Adelaide river virus has intergenic regions of 1 to 4 nucleotides, lacks the *γ* gene and has a β–L overlap. The functions of the products of the *α1*, *α2*, *β*, and *γ* genes have not been identified. Gns is a nonvirion glycoprotein and may be analogous to the soluble G proteins of some paramyxoviruses and ebolaviruses, but it does not induce neutralizing antibodies and is not protective, causes economically important enzootic disease of cattle and is transmitted by, and replicates in, hematophagous arthropods. The genus *Novirhabdovirus* comprises three virus species infecting aquatic hosts: *Infectious hematopoietic necrosis virus*, *Hirame rhabdovirus*, and *Viral hemorrhagic septicemia virus*. These viruses encode the standard rhabdovirus complement of five structural protein genes, plus a sixth nonvirion (NV) protein gene of unknown function located between the *G* and *L* genes. There is a 60 nucleotide leader sequence, a 100 nucleotide trailer, and single nucleotide intergenic regions. The N protein sequence identity between these species is about 34 percent and there is no cross-neutralisation. The genus *Cytorhabdovirus* comprises eight species of plant rhabdoviruses, which multiply in the cytoplasm in association with thread-like structures (viroplasms). They are transmitted by arthropod vectors (predominantly leafhoppers and aphids), and most appear to be able to multiply in the arthropod vector as well as the host plant. The gene order of the type species, *Lettuce necrotic yellows virus*, is 3′-N–P(4a)–4b–M–G–L–5′ with an 84 nucleotide leader and a 187 nucleotide trailer. The *4b* gene is thought to encode a nonstructural protein. The genus *Nucleorhabdovirus* comprises seven species of plant viruses, which multiply in the nucleus of plant cells forming large granular inclusions. Virus morphogenesis occurs at the inner nuclear envelope and enveloped particles accumulate in the perinuclear space. The genome order is similar to that of the cytorhabdoviruses, except that the nonstructural protein gene is designated *SC4*, and there is an additional gene between the *G* and *L* genes in *Rice yellow stunt virus* which encodes a virion-associated protein. There is a 114 nucleotide leader and a 160 nucleotide trailer. Like the cytorhabdoviruses, the nucleorhabdoviruses are predominantly transmitted by leafhoppers and aphids.

In addition to the rhabdoviruses assigned to genera, there at least six serogroups of rhabdoviruses whose taxonomic affiliations are indeterminate at present. There are also more than 37 ungrouped animal viruses that have been propagated and characterized to varying extents, and another 58 plant viruses of uncertain status because their identification is based often on morphological evidence only. Some of the ungrouped animal viruses, such as the arthropod-borne Obodhiang virus and Kotonkan virus previously included in the genus *Lyssavirus*, have been excluded from earlier classifications as knowledge of their uniqueness accrues. Perhaps the most significant of the ungrouped animal rhabdoviruses is Sigma virus, which is transmitted vertically through the germ cells of *Drosophila* spp. conferring CO_2 sensitivity on the infected insect. Both host and viral genes contribute to maintenance of the virus in the host. The Sigma virus genome has an *M–G* gene overlap, variable intergenic regions, and encodes a sixth gene of unknown function, but with motifs related to reverse transcriptase motifs, located between the *P* and *M* genes (see also Rhabdoviruses: rabies).

Table 3 provides a diagrammatic representation of the 3′ to 5′ characteristic arrangement of the transcriptional elements of the genomes of viruses classified in the four families comprising the order *Mononegavirales.*

THE CONSERVATION OF GENE ORDER

The conservation of a preferred gene order is one of the striking and unifying features of the order *Mononegavirales* (Table 3). The order of their genes is the major determinant of the relative levels of gene expression, since genes that are close to the 3′ promoter site are transcribed at higher levels than those that occupy more distal positions. Genetic manipulation of an infectious cDNA clone of vesicular stomatitis Indiana virus resulted in production of viable viruses with rearrangements of gene order, which left the viral nucleotide sequence otherwise unaltered (Ball et al. 1999). The

three central genes in the gene order, which encode *P*, *M*, and *G*, were rearranged in all six possible configurations. All six rearrangements were propagated stably as infectious virus and each rearrangement had changed the expression levels of the encoded proteins in accordance with their relative proximity to the 3′ promoter. Similarly, translocation of the *N* gene away from its promoter proximal location to successive positions down the gene order reduced N mRNA and protein expression in a step-wise manner (Wertz et al. 1999). Remarkably, some of the viruses with rearranged genomes replicated as well as or slightly better than the unrearranged wild type virus. Despite the highly conserved gene order of the *Mononegavirales*, gene rearrangement is neither lethal nor necessarily detrimental.

Furthermore, moving the attachment protein gene (*G*) from fourth to first position in the gene order of vesicular stomatitis virus increased expression of the G protein and enhanced the kinetics and level of antibody response in mice infected with this gene order variant (Flanagan et al. 2000). Similar experiments have shown that vesicular stomatitis Indiana virus can tolerate the insertion of duplicated or heterologous genes into the gene order (Wertz et al. 2002), thereby opening up new routes to vaccine development. In general, the nonstandard gene rearrangements and the inserted genes were stably maintained in the modified genomes on repeated passage. The absence of a mechanism for homologous recombination in negative-sense RNA viruses may be responsible for the maintenance of a preferred gene order in evolution, but the reason for choice of the particular gene order adopted by the *Mononegavirales* is an enigma.

PHYLOGENY OF THE ORDER *MONONEGAVIRALES*

The determination of the nucleotide sequences of specific genes, and in many cases the complete genomes, of many members of the order *Mononegavirales* has allowed an analysis of the molecular phylogeny of this group of viruses (Figure 1a). While in principle a phylogenetic analysis can be performed with any of the genes shared by all members of the *Mononegavirales*, it is most appropriate to use sequences of internal proteins as these are least affected by the selective pressure of antibody surveillance in the host. Of the internal protein genes, the most conserved is that encoding the RNA polymerase, the L protein. A comparison of the polymerase protein genes of a number of nonsegmented viruses identified four conserved domains (Poch et al. 1989, 1990; Le Mercier et al. 1997). Domain III contains four conserved motifs, including the GDNQ motif associated with polymerase activity (Figure 1b). A phylogenetic tree constructed using the sequences of the RNA polymerase conserved domain III of a representative selection of viruses is shown in Figure 1a. This analysis shows clearly the phylogenetic divisions of the different virus groups represented in the ICTV classification system. The families *Paramyxoviridae*, *Bornaviridae*, *Rhabdoviridae*, and *Filoviridae* segregate into different lineages, presumably linked by a common ancestor. Within the family *Paramyxoviridae*, the two subfamilies *Paramyxovirinae* and *Pneumovirinae* can be seen to segregate and within each the genera are clearly distinct, though related. Molecular phylogeny has confirmed the relationship of the viruses assigned to the order *Mononegavirales* on the basis of a number of physical and biochemical parameters and now allows a rapid classification of newly isolated viruses. This approach has recently led to the identification of new genera, the genus *Avulavirus* and the genus *Henipavirus*. Figure 1 also shows the phylogenetic relationship of three currently unassigned viruses to the other members of the *Paramyxovirinae*. *Avian paramyxovirus 6* appears to be related most closely to *Newcastle disease virus* (also known as *avian paramyxovirus 1*), whereas Tioman virus and Tupaia paramyxovirus are closest to the rubulaviruses and morbilliviruses, respectively.

INTRODUCTION

Nidovirus infections in both animals and man result in a variety of diseases that may range from relatively benign to fatal. The order *Nidovirales* (Figure 1) is comprised of the genus *Coronavirus*, which together with the genus *Torovirus* forms the *Coronaviridae* family, and the families *Arteriviridae* and *Roniviridae*. The biological and pathogenic properties of individual coronaviruses, toroviruses, and arteriviruses are summarized in . In this chapter, we present a comparative overview of nidoviruses that has three major goals. First, this broader approach presents our knowledge of human coronaviruses in an evolutionary perspective, thus preparing the ground for further expansion of a cluster of viruses that contains pathogens responsible for emerging infections. Second, it highlights the parallels and homologies amongst nidoviruses and, as such, forms a common framework for studies on animal models and human nidovirus infections. Third, it provides an overview of both unique and conserved nidovirus properties, thus highlighting potential targets for the development of reagents to detect and combat nidovirus infections.

Over the past 20 years, molecular biology and genetics have contributed enormously to the characterization of viruses and, at the same time, changed the face of virus taxonomy. It has become increasingly evident that the comparative analysis of virus genomes provides a better foundation for comprehensive virus taxonomy than more traditional parameters, such as virion morphology or host range. This realization has resulted in the reclassification of specific viruses (or groups of viruses) and also in the introduction of higher order taxa to recognize evolutionary ties that surpass the level of the virus family.

Besides the order *Nidovirales*, only two other virus orders have been recognized thus far. The order *Caudovirales* unites several families of tailed DNA viruses of bacteria (bacteriophages) and the order *Mononegavirales* is comprised of three virus families with a negative-strand RNA genome that consists of one single-stranded RNA segment. The order *Nidovirales* was established by the International Committee on the Taxonomy of Viruses (ICTV) in 1996 (Cavanagh 1997). At that time, it united the newly established family *Arteriviridae* with the pre-existing family *Coronaviridae* (containing the genera *Coronavirus* and *Torovirus*). As will be explained below, the inclusion of these groups of positive-strand RNA viruses in the order *Nidovirales* recognized striking similarities at the level of genome organization and expression, and the intriguing phylogenetic clustering of their giant replicase polyproteins, the precursors to the key enzymes that drive virus replication (Gorbalenya et al. 1989; den Boon et al. 1991). More recently, and on the same grounds, the order *Nidovirales* was expanded to include the family *Roniviridae* (Walker et al. 2004; Spaan et al. 2005), which currently comprises a single genus, *Okavirus*. Whereas other known nidoviruses infect

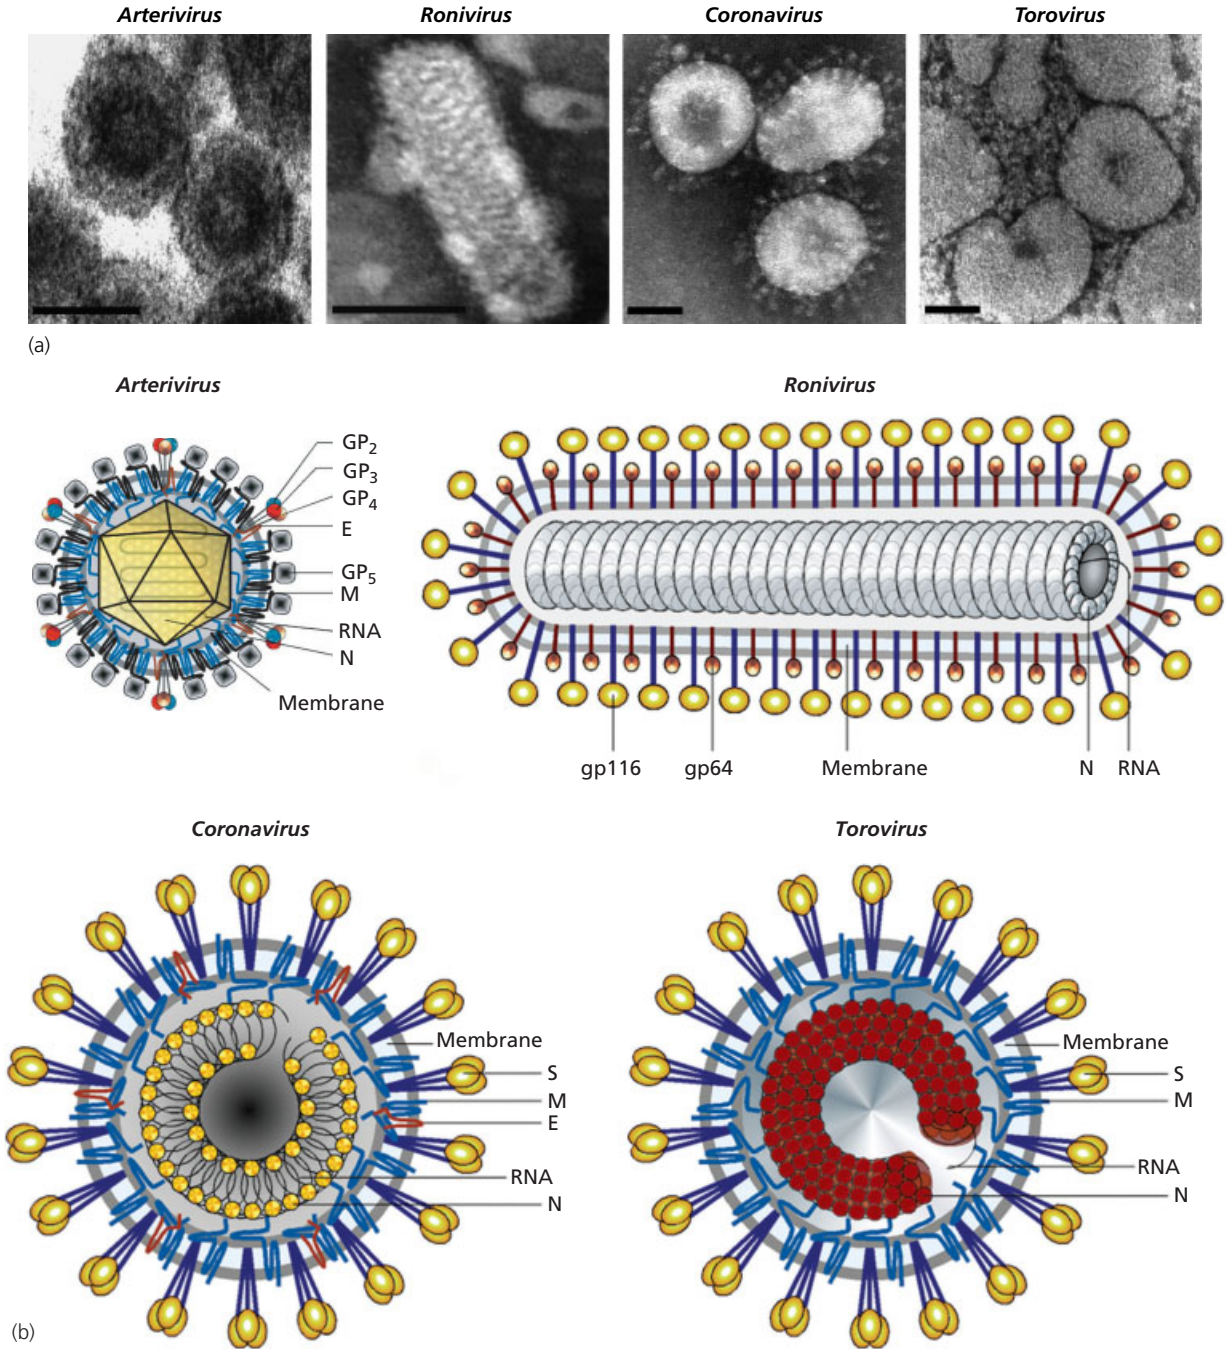

Figure 1 *Electron micrographs* **(a)** *and schematic representations* **(b)** *of nidovirus structure.* **(a)** *Characteristic images of negatively stained arterivirus, ronivirus, coronavirus, and torovirus particles, as captured with a transmission electron microscope. The diverse size and different structural features of representatives of the four main nidovirus branches are evident. Images were reproduced (with permission) from Snijder and Meulenberg (1998), arterivirus; Spann et al. (1995), ronivirus; Dr. Fred Murphy, Centers for Disease Control and Prevention (CDC), Atlanta, USA, coronavirus; and Weiss et al. (1983), torovirus. Bar is 50 nm.* **(b)** *Schematic representation of arterivirus, ronivirus, coronavirus, and torovirus virion structure. The different symmetries of the nucleocapsid structures and virions are indicated (see for more details). Viral membrane proteins present in the virion envelope are depicted. Note that some viruses have been found to contain additional envelope proteins, e.g. the hemagglutinin esterase (HE) protein identified in certain coronaviruses and toroviruses. The stoichiometry of the virion components is shown (more or less) arbitrarily. N, nucleocapsid protein; M, membrane protein; S, spike protein; E, envelope protein; GP or gp, glycoprotein.*

vertebrate hosts (mostly mammals and some avian hosts), roniviruses infect invertebrates, specifically prawns. Nevertheless, their molecular biological features and elements of their genetic plan clearly link them to arteriviruses and coronaviruses (Cowley et al. 2000). The expansion of the *Nidovirales* with new viruses, and the extensive characterization of a few nidoviruses over recent years, have resulted in a refinement and partial

revision of the framework of specific and conserved features that defines this virus order.

MAJOR NIDOVIRUS BRANCHES AND THEIR PROTOTYPE VIRUSES

For obvious reasons, the best-studied nidoviruses are the viruses that either cause significant disease in humans or livestock and/or are most easily studied in cell culture or small animal model systems. In the family *Coronaviridae* (Lai and Cavanagh 1997; Lai and Holmes 2001), the prototype of the genus *Coronavirus* is the avian *Infectious bronchitis virus* (IBV), although *Murine hepatitis virus* (MHV), has probably been more extensively studied. Modest attention has also been paid to the two human common cold viruses, HCoV-229E and HCoV-OC43. The recent emergence of a third human coronavirus, which was identified as the cause of severe acute respiratory syndrome (SARS), has boosted research on human coronaviruses in general (Drosten et al. 2003; Ksiazek et al. 2003; Peiris et al. 2003a). Currently, many aspects of SARS-coronavirus (SARS-CoV) and the disease that it causes are being characterized at an unprecedented rate (Stadler et al. 2003; Peiris et al. 2003b; Berger et al. 2004; Ziebuhr 2004a). The identification of a fourth human coronavirus (NL63 and HKU1) (van der Hoek et al. 2004; Fouchier et al. 2004; Woo et al. 2005), which are relatively closely related to previously identified group 1 and group 2 coronaviruses, respectively, was recently reported, and the detection of additional human coronaviruses can be expected now that the significance of this group of viruses has been recognized in the wake of the SARS outbreak.

Animal coronaviruses that have been studied quite extensively because of the respiratory and/or enteric disease that they cause in livestock or companion animals are IBV, *Bovine coronavirus* (BCoV), porcine *Transmissible gastroenteritis virus* (TGEV), and *Feline coronavirus* (FCoV or FIPV). In the genus *Torovirus* (Snijder and Horzinek 1993), the *Equine torovirus* (EToV) (or Berne virus) is the sole representative, thus far, that can be amplified and studied in cultured cells. Bovine, porcine, and possibly human toroviruses have been identified but have not yet been propagated in cell culture. The name coronavirus is derived from the solar corona-like (Latin *corona*: crown) appearance of virus particles in negatively stained electron micrographs, whereas the name torovirus is derived from the curved tubular (Latin torus: lowest convex molding in the base of a column) morphology of the torovirus nucleocapsid structure (Figure 1a).

The outcome of arterivirus infection can range from an asymptomatic, persistent carrier-state to lethal hemorrhagic fever. The arterivirus family (Plagemann 1996; Snijder and Meulenberg 1998; Snijder and Meulenberg 2001) currently consists of a single *Arterivirus* genus with four virus species, of which the prototype *Equine arteritis virus* (EAV) is the best-studied representative in terms of molecular biology. Arteritis (inflammation of an artery), one of the disease symptoms caused by EAV, gave the arterivirus family its name. EAV and the *Porcine reproductive and respiratory syndrome virus* (PRRSV), of which different genotypes emerged in Europe and North America during the late 1980s, are the two arteriviruses that cause significant disease in livestock. Arteriviruses spread primarily via the respiratory route, but sexual transmission by persistently infected animals is an important secondary cause of infection in the case of EAV and PRRSV.

In the family *Roniviridae* (for *ro*d-shaped *ni*dovirus), the prototype of the genus *Okavirus* is the Gill-associated virus (GAV) (Spann et al. 1995; Cowley et al. 2000) of which the black tiger prawn (*Penaeus monodon*) appears to be the natural host. GAV can cause devastating infections in cultured prawns, where it targets the lymphoid organ (or 'oka') in particular.

KEY COMMON FEATURES OF NIDOVIRUSES

Nidoviruses are enveloped, positive-strand RNA viruses that share a similar genome organization and similar replication strategy (Figure 2) that is driven by the gene encoding the large nonstructural or 'replicase' proteins. Phylogenetic analysis of key domains in the nidovirus replicase gene revealed that these elements are much more closely related to each other than to the corresponding sequences in the genomes of other positive-strand RNA viruses (see below and Figure 3 for details). Thus, the nidovirus replicase represents a separate lineage in RNA virus evolution (den Boon et al. 1991; Gorbalenya and Koonin 1993; Gorbalenya et al. 1989).

Nidoviruses have diverged profoundly since they originated from their common root. They differ significantly in terms of the size of their genome, virion morphology, host range, and various biological properties. However, a number of features, although not diagnostic of this virus order alone, are thought to be common to nidoviruses. Still, it should be noted that, in particular for toroviruses and roniviruses, many of these properties have not been studied in great detail and the list below may be subject to future updates.

- Nidoviruses have positive-strand RNA genomes consisting of one single-stranded, linear RNA molecule that contains a 5′ cap structure and a 3′ poly(A) tail.
- The general nidovirus genome organization (with some exceptions) is: 5′ untranslated region – replicase – envelope proteins – nucleocapsid protein – 3′ untranslated region (however, note that the ronivirus N protein gene is located upstream of the envelope protein gene (Cowley et al. 2004)).

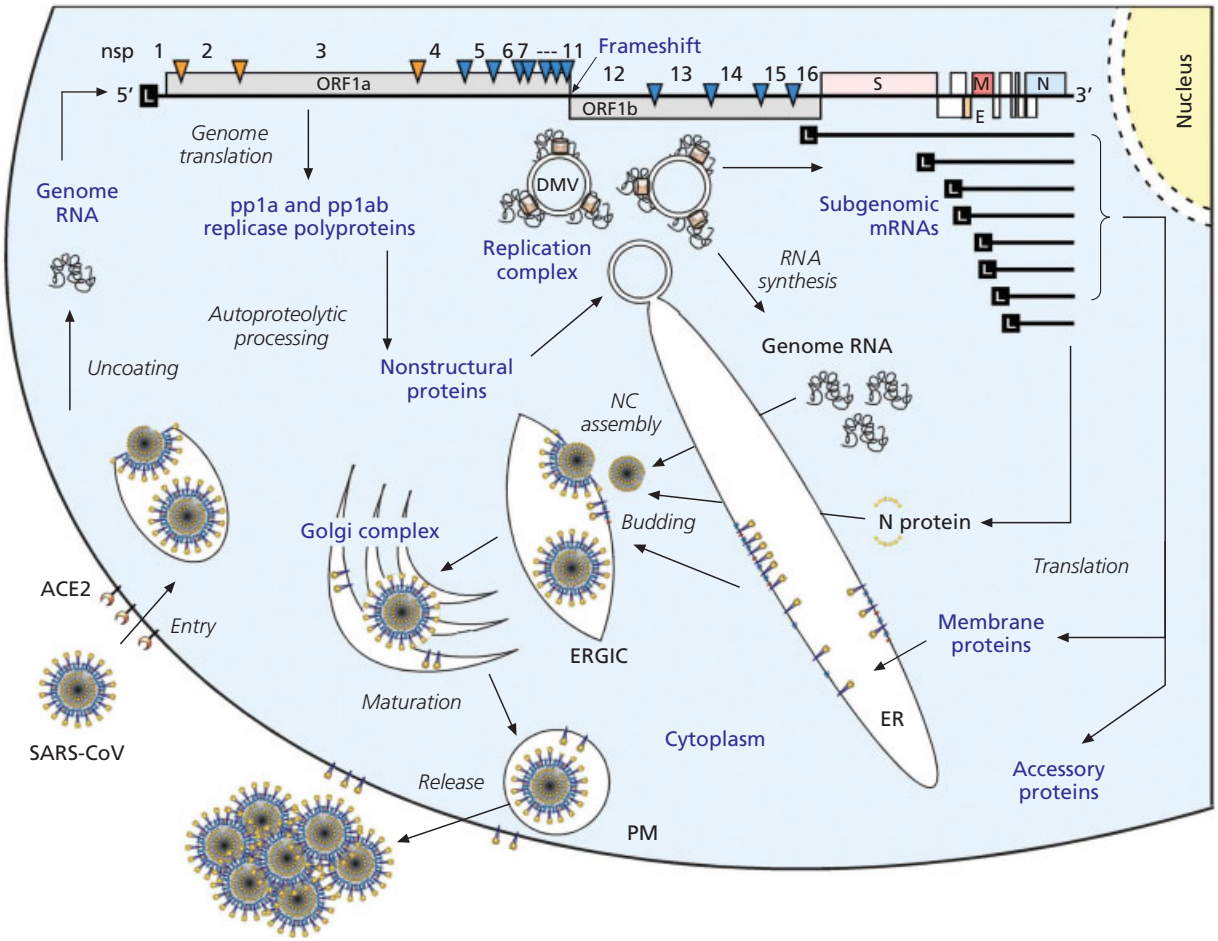

Figure 2 *Overview of the nidovirus life cycle, using SARS-CoV as an example. Depicted is the cytoplasmic replication cycle of a typical coronavirus (see text and for more details). Infection starts with binding of the virus to a specific receptor on the host cell's plasma membrane (PM) (in this case angiotensin-converting enzyme 2 (ACE2)), entry by fusion of viral envelope and cellular membrane, and release of the viral plus-strand RNA genome into the cytoplasm. Subsequently, the genome is translated by host ribosomes to produce the polyprotein precursors (pp1a and pp1ab) to the nonstructural proteins (nsp) that drive viral RNA synthesis. Following limited autoproteolysis of these 'replicase' polyproteins, a complex for viral RNA synthesis is assembled on cytoplasmic double-membrane structures (double-membrane vesicles (DMVs)). This complex produces minus-strand RNAs (not shown) that serves as template for genome replication and the synthesis of a nested set of subgenomic mRNAs. The latter, which contain a common leader sequence (L) identical to the 5′ end of the genome, are translated to express the genes that are encoded in the 3′-proximal third of the genome. Translation of the smallest subgenomic mRNA yields the viral nucleocapsid protein (N) that assembles into new nucleocapsid (NC) structures together with newly generated genome RNA. Other subgenomic mRNAs encodes viral envelope proteins that are (largely cotranslationally) inserted into membranes of the host cell's exocytic pathway and migrate towards the site of virus assembly (the ER–Golgi intermediate compartment (ERGIC) in the case of coronaviruses). Following budding of the NC through membranes that contain viral envelope proteins, the new virion ends up in the lumen and, while undergoing additional maturation steps in, for example, the Golgi complex, leaves the cell via the exocytic pathway.*

- The nidovirus replicase gene comprises two large and overlapping open reading frames (ORF) that encode the replicase polyproteins pp1a and pp1ab. Expression of the downstream ORF1b is mediated by programmed −1 ribosomal frameshifting (FS).
- An RNA structure (slippery sequence plus RNA pseudoknot) mediates programmed ribosomal frameshifting in the ORF1a/1b overlap region (Brierley et al. 1989).
- In the infected cell, nidovirus gene expression is mediated by a set of at least three 3′ co-terminal subgenomic mRNAs that are thought to be produced from a set of complementary templates of the same sizes. Generally, only the ORFs contained within the 5′ unique regions of each mRNA, i.e. the regions not found in the next smallest mRNA are expressed.
- Viral RNA synthesis occurs on intracellular, virus-induced (double) membrane structures.
- Nidovirus particles contain a lipid envelope.
- The envelope of nidovirus particles contains an integral, triple-spanning membrane (m) protein.
- Nidovirus particles are assembled intracellularly, by budding into the lumen of membrane-bound organelles.

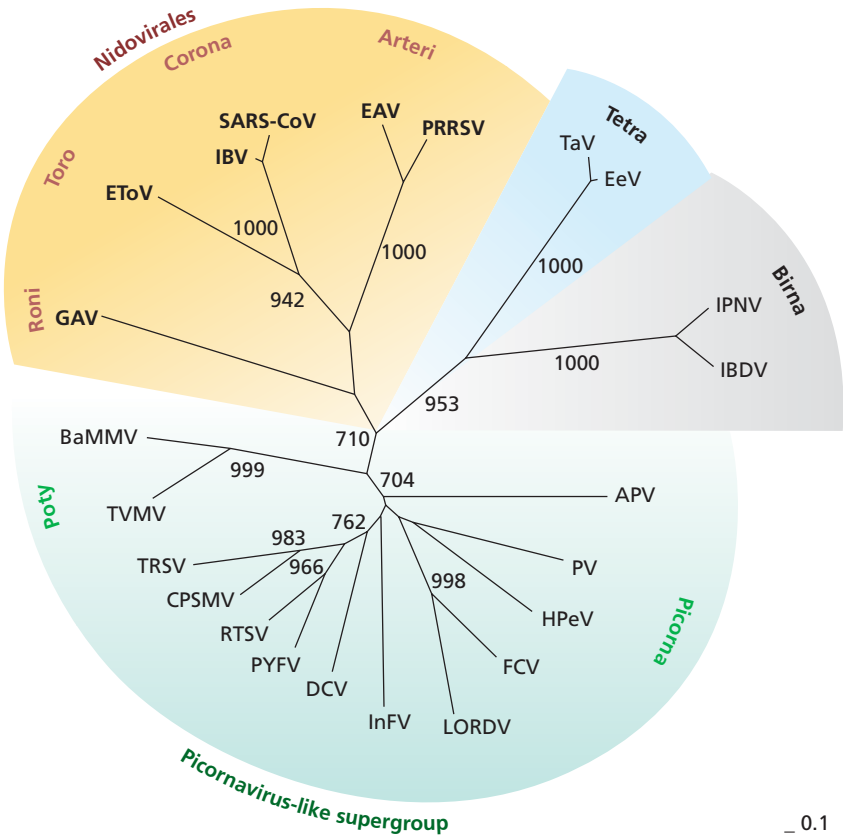

Figure 3 *Unrooted phylogenetic tree of RNA-dependent RNA polymerase (RdRp) domains of* Nidovirales *and other (super)groups of positive-strand and double-stranded RNA viruses. The most conserved part of RdRps from representative viruses in the* Picornaviridae, Dicistroviridae, Sequiviridae, Comoviridae, Caliciviridae, Potyviridae, Coronaviridae, Roniviridae, Arteriviridae, Birnaviridae, Tetraviridae, *and unclassified insect viruses was aligned. An unrooted neighbor-joining tree was inferred by the ClustalX1.81 program. For details of the analysis, see Gorbalenya et al. (2002). All bifurcations with support in >700 out of 1 000 bootstraps are indicated. Different groups of viruses are highlighted with different colors. The tree was modified from Gorbalenya et al. (2002) and Spaan et al. (2005). Virus families/groups and abbreviations of viruses included in the analysis:* Coronaviridae*: avian infectious bronchitis virus (IBV), severe acute respiratory syndrome virus (SARS-CoV) and equine torovirus (EToV);* Arteriviridae*, equine arteritis virus (EAV) and porcine reproductive and respiratory syndrome virus strain VR-2332 (PRRSV);* Roniviridae*: gill-associated virus (GAV);* Picornaviridae*, human poliovirus type 3 Leon strain (PV) and parechovirus 1 (HPeV); iflavirus, infectious flacherie virus (InFV); unclassified insect viruses, Acyrthosiphon pisum virus (APV);* Dicistroviridae*, Drosophila C virus (DCV);* Sequiviridae*, rice tungro spherical virus (RTSV), and Parsnip yellow fleck virus (PYFV);* Comoviridae*, cowpea severe mosaic virus (CPSMV) and tobacco ringspot virus (TRSV);* Caliciviridae*, feline calicivirus F9 (FCV), and Lordsdale virus (LORDV);* Potyviridae*, tobacco vein mottling virus (TVMV) and barley mild mosaic virus (BaMMV);* Tetraviridae*, Thosea asigna virus (TaV) and Euprosterna elaeasa virus (EeV);* Birnaviridae*, infectious pancreatic necrosis virus (IPNV) and infectious bursal disease virus (IBDV).*

Nidoviruses also share a number of unique features that could be considered as genetic markers of this order. All of them are associated with the replicase gene, which contains a conserved series of key functional domains (a constellation abbreviated as M–3CLpro-M–FS–RdRp–ZF–HEL–NendoU; see below) including:

- A cluster of domains, encoded by ORF1a, consisting of a main proteinase (3C-like proteinase; 3CLpro), which has a chymotrypsin-like fold and substrate specificity resembling that of picornavirus 3C proteinases, and flanking transmembrane (M) domains (M-3CLpro-M);
- An ORF1b-encoded protein that combines an N-terminal (putative) multinuclear zinc-finger (ZF) domain with a C-terminal NTP-binding/5′-to-3′-helicase domain (HEL);
- An ORF1b-encoded uridylate-specific endoribonuclease (NendoU).

The exact role of these unique genetic markers in the nidovirus life cycle remains largely unknown. The presence of a common ‘leader’ sequence at the 5′ end of all viral mRNA species (Spaan et al. 1983; Baric et al. 1983; Lai et al. 1984; de Vries et al. 1990) was initially considered a major hallmark of nidoviruses, but recently proved to be a property that is not universally conserved

amongst members of this virus order (Cowley et al. 2002; van Vliet et al. 2002).

MAIN DIFFERENCES BETWEEN MAJOR NIDOVIRUS BRANCHES

Despite the common features of their genome and molecular biology (see also below), evolutionary distances within the order *Nidovirales* are vast and there are major differences between the virus families and genera that are united in this taxon. A striking difference that separates the arteriviruses from other nidoviruses is the smaller size of their genome (12.7 to 15.7 kb versus more than 27 kb for the other nidoviruses). Accordingly, the arterivirus replicase polyproteins are less than half the size of their coronavirus, torovirus, and ronivirus counterparts. Despite this difference, coronaviruses and arteriviruses share a common property that is not conserved in toroviruses and roniviruses, as they have a common leader sequence at the 5′ end of all viral mRNAs, genomic and subgenomic.

Most of all, however, the features that distinguish the various nidovirus branches from each other are found at the level of virion structure and the properties of structural proteins (see Figure 1 and for details). Arterivirus are spherical with a diameter of about 60 nm and lack prominent surface projections. Coronavirus particles have a diameter of 120–140 nm (including the extended peplomers). Toroviruses have a virion size similar to coronaviruses, while the bacilliform ronivirus particles are 150–200 nm long, have a diameter of 20–30 nm, and are also studded with prominent peplomers projecting approximately 11 nm from the surface. The nucleocapsid structure is helical–spherical for coronaviruses, helical–tubular for toroviruses and roniviruses, and isometric for arteriviruses. The nucleocapsid proteins of the four virus groups do not appear to share any common ancestry and their sizes range from 50 to 60 kDa for coronaviruses to only 12–14 kDa for arteriviruses. Also, the number of viral envelope proteins is quite variable, ranging from a single, post-translationally cleaved spike glycoprotein in roniviruses to a combination of six integral envelope proteins in arteriviruses. Whereas coronaviruses, toroviruses, and roniviruses carry a prominent spike structure (an oligomer of the S protein) on their surface, such structures have not been observed for arteriviruses. However, a common feature of all nidoviruses is the presence of an integral, triple-spanning membrane (M) protein in the viral envelope, which plays a crucial role during virus assembly.

A final difference that should be highlighted is the presence of genes encoding so-called 'accessory proteins' in coronavirus genomes. In the case of arteriviruses, toroviruses, and probably also roniviruses, all genes downstream of the replicase gene encode structural proteins. However, in coronaviruses several nonstructural proteins are encoded in this part of the genome. These genes differ (in terms of position and protein encoded) between the different subgroups that are recognized among coronaviruses (for example, see the small undesignated genes dispersed among the *S*, *E*, *M*, and *N* protein genes in the 3′ proximal region of the SARS-CoV genome in Figure 2). A common feature, however, is that these genes appear to be dispensable for replication in cell culture. This suggests that the products of these genes exert their function at the level of the interaction with the host and may be important for the virus in, for example, countering antiviral responses triggered by the infection.

GENERAL SCHEME OF THE NIDOVIRUS LIFE CYCLE

Our knowledge of the nidovirus life cycle is largely based on cell culture-based studies with a limited number of viruses from the arterivirus and coronavirus families. Consequently, the description that follows (and the example of the SARS-CoV life cycle presented in Figure 2) should not be considered as definitive for all nidoviruses.

Nidoviruses attach to their host cell by binding to a receptor on the cell surface. These host molecules are mostly proteins, but in some cases carbohydrates may be involved. A number of cellular receptors have been identified and studied in detail for coronaviruses (Yeager et al. 1992; Williams et al. 1991; Li et al. 2003) and for the arterivirus PRRSV (Vanderheijden et al. 2003). Fusion of the nidoviral and cellular membrane is mediated by one of the major surface glycoproteins. Since the spike (S) protein of several coronaviruses displays fusion activity at neutral pH, fusion of the viral envelope and the plasma membrane is considered to be one route of entry for this virus group. However, endocytosis of coronaviruses has been described, which is the same infection route used by arteriviruses. Fusion of the viral envelope and a cellular membrane (either plasma membrane or endosome) results in the release of the viral nucleocapsid into the cytoplasm of the host cell (see for details). Uncoating of the viral genome, which must precede genome translation, has not been studied in any detail.

The nidovirus genome is translated by host ribosomes that bind to the cap structure at the 5′ end of the genomic RNA and subsequently scan the template to find the translation initiation codon of replicase ORF1a. Following ORF1a translation, 60–80 percent of the ribosomes terminate at the ORF1a stop codon. However, the remaining ribosomes shift into the −1 reading frame just upstream of the ORF1a stop codon, at a specific heptanucleotide sequence (the slippery sequence), and continue translation in replicase ORF1b (Brierley et al. 1989; Snijder et al. 1990a; den Boon et al. 1991; Cowley et al. 2000). Consequently, genome translation leads to the synthesis of two replicase polyproteins, pp1a and pp1ab,

with pp1ab being a carboxyl-extended version of pp1a. The −1 frameshift is stimulated by an RNA pseudoknot structure (i.e. two stem–loop structures that interact by base-pairing between sequences in the loops of the two hairpins) that probably induces a ribosomal pause over the slippery sequence. Due to the ribosomal frameshift mechanism, the ratio between translation of ORF1a and ORF1b is constant, which is thought to be an important part of the regulation of nidovirus replicase expression.

Nascent replicase polyproteins have never been detected in nidovirus-infected cells due to the speed of autoproteolytic processing, which seems to be initiated before the completion of ORF1a translation. The processing of the N-terminal 20–25 percent of the pp1ab polyprotein, is controlled by one or more so-called accessory proteinases that initiate autoproteolysis, while the main proteinase (3CLpro) is responsible for the processing of the downstream and most conserved part of the polyproteins (reviewed by Ziebuhr et al. (2000)). The accessory proteinase domains are located in the ORF1a-encoded region of the replicase and belong to the papainlike superfamily of cysteine proteinases (Gorbalenya et al. 1991). They are either autoproteinases that liberate the replicase subunit of which they are part (arteriviruses), or they can cleave up to three sites in the N-terminal half of pp1a (coronaviruses). The C-terminal half of pp1a and the ORF1b-encoded part of pp1ab are cleaved at eight to 11 sites by the viral main proteinase, which belongs to the chymotrypsin-like superfamily of proteinases (Gorbalenya et al. 1989; Snijder et al. 1996; Ziebuhr et al. 2003; Anand et al. 2002; Barrette-Ng et al. 2002). Replicase proteolysis is a crucial and probably highly regulated process, which should produce the right cleavage products in the right amounts at the right moment. The number of mature replicase products (nonstructural proteins or nsps) ranges from 12 or 13 in arteriviruses to 16 in most coronaviruses. By analogy with other RNA viruses, it may be expected that certain processing intermediates also have specific functions in the nidovirus life cycle.

Either during or shortly after translation, and possibly regulated by proteolytic cleavages, most of the nidovirus replicase proteins associate with intracellular membranes to form a membrane-bound complex for RNA synthesis ('replication complex'), a common feature of animal positive-strand RNA viruses. A number of ORF1a-encoded subunits contain hydrophobic domains and become transmembrane proteins, although they cannot be classified as 'conventional' membrane proteins (e.g. a signal sequence is lacking) and their mode of membrane insertion is unclear. For arteriviruses, it has been shown that the expression of two of these proteins (nsp2 and nsp3) suffices to induce the formation of specific double membrane vesicles, which seem to be derived from the endoplasmic reticulum and carry the viral replication complex (Pedersen et al. 1999; Snijder et al. 2001). Similar structures have been identified in cells infected with coronaviruses (Gosert et al. 2002), although other studies implicated late endosomes (van der Meer et al. 1999) or autophagosomes (Prentice et al. 2004) in the formation of the coronavirus replication complex. Other replicase subunits lack hydrophobic sequences, but immunofluorescence and electron microscopy has revealed that most of them co-localize with the ORF1a-encoded transmembrane subunits. Thus, the latter are likely to form a membrane-bound scaffold for the replication complex.

The first step in viral RNA synthesis is the recognition of RNA signals that promote the association of the 3′ end of the viral genome with a complex of viral enzymes that includes the RNA-dependent RNA polymerase encoded in the 5′-proximal part of replicase ORF1b. This 'RdRp complex' initiates the synthesis of full-length minus-strand RNA (or antigenome), which in turn will be the template for the synthesis of novel genome RNA. For the latter process, recognition signals present in the 3′ end of the antigenome must be used (see
for details). The amplification of the viral RNA is asymmetric and results in the production of much more plus- than minus-strand RNA. In coronavirus-infected cells, the structures engaged in viral RNA synthesis have been characterized. Approximately 70 percent of the RNA structures that accumulate in infected cells are multi-stranded intermediates (replicative intermediates) and 30 percent are double-stranded structures (replicative forms). These estimates describe, essentially, the structures involved in plus-strand synthesis. The structures engaged in minus-strand synthesis have not yet been characterized, although it is known that minus-strand templates are unstable and turnover during viral replication (Sawicki et al. 2001).

The newly synthesized genome RNA may be utilized in translation, replication, subgenomic mRNA synthesis, and/or encapsidation. First, genome RNA is used for translation of replicase ORFs 1a and 1b, thus yielding the polyprotein precursors of the main components of the viral replicase/transcriptase complex. Second, genome RNA serves as template for antigenome synthesis in the asymmetric cycle of genome replication described above. Third, genome RNA is assumed to be the template to produce subgenome-length minus strands that are used as templates for subgenomic mRNA synthesis. A nested set of subgenomic mRNAs is produced to express the viral structural proteins (and sometimes also accessory proteins) from genes located in the 3′-proximal third of the genome (the region downstream of ORF1b), which remains inaccessible for ribosomes translating the genome RNA. The synthesis of nidovirus subgenomic mRNAs was studied extensively and this will be discussed in a separate paragraph below. Finally, the de novo synthesized genomes can be used for encapsidation into progeny virions at the end of the infection cycle.

Following the accumulation of the structural proteins, the components for new virus particles have to assemble

in the infected cell. New genomes first associate with the cytoplasmic nucleocapsid protein to form nucleocapsid structures. The viral envelope proteins are inserted into intracellular membranes, mostly by conventional cotranslational translocation. Subsequently, the envelope proteins are targeted to the site of virus assembly (usually membranes between the endoplasmic reticulum and Golgi complex; see for details). Here, they meet up with the nucleocapsid structure and trigger a budding process that results in the envelopment of the nucleocapsid by host membrane impregnated with viral envelope proteins. As a result of budding, the newly formed virus particle is located in the lumen of the membrane compartment, after which it can leave the cell by following the exocytic pathway towards the plasma membrane. During this process, additional maturation of viral proteins and/or carbohydrates attached to these proteins occurs, in particular during transit through the Golgi complex.

THE NIDOVIRUS REPLICASE/ TRANSCRIPTASE

The synthesis of nidovirus-specific RNAs is mediated by a molecular machinery known as replicase/transcriptase (for simplicity often referred to as 'replicase'), which has not been characterized in detail for any nidovirus. Much of what is currently known about this macromolecular complex derives from comparative sequence analysis (reviewed in (Gorbalenya 2001); see below) that implicated ORF1a and 1b in encoding the key elements of the nidovirus replicase/transcriptase. This prediction has only recently been verified experimentally using genetic methods for the arterivirus EAV and the coronaviruses HCoV-229E and MHV (van Dinten et al., 1997, 1999; Tijms et al. 2001; Thiel et al. 2001; Seybert et al. 2005; Ivanov et al. 2004; Siddell et al. 2001).

The nidovirus replicase gene forms the backbone of the unique genetic plan that unites the different nidovirus subgroups (den Boon et al. 1991; Gorbalenya and Koonin 1993; Gorbalenya et al. 1989). From the end of the 1980s and through the 1990s, sequence analysis of different coronavirus, arterivirus, and torovirus genomes revealed a genetic plan consisting of nontranslated regions at the 5′ and 3′ ends of the genome that flank six to 11 ORFs, some of which are partly overlapping. The 5′-proximal two-thirds of the nidovirus genome is dominated by the replicase ORFs that encode the large pp1a and pp1ab polyproteins. These polyproteins are organized around a conserved framework of a dozen replicative domains and are autocatalytically processed to numerous products at conserved interdomain junctions (Ziebuhr et al. 2000). The other ORFs, whose number varies in different viruses, are located further downstream and a nested set of subgenomic mRNAs is generated to allow their expression.

The first nidovirus genome to be fully sequenced was that of the coronavirus IBV (Boursnell et al. 1987). Pairwise and profile comparisons of the IBV pp1a/pp1ab with replicative proteins of positive-strand RNA viruses and selected cellular proteins (Gorbalenya et al. 1988, 1989) tentatively identified a total of eight domains and 13 sites of proteolytic autoprocessing in pp1a/pp1ab. This analysis proved to be quite accurate and was largely confirmed by subsequent experimental studies. In the ORF1a-encoded sequence, a 3CLpro was recognized that is flanked by two highly hydrophobic, presumably transmembrane domains. Downstream of the ORF1a/1b ribosomal frameshift site, sequences encoding a putative RdRp and a putative superfamily 1 helicase (HEL1), the latter linked to an upstream-positioned Cys/His-rich domain predicted to form a multi-nuclear Zn-finger (ZF), were correctly identified.

Three domains identified in IBV, namely 3CLpro, RdRp, and HEL1, were (distant) variants of domains that are ubiquitous in the replicative polyproteins of positive-strand RNA viruses. Like their counterparts in other viruses, the IBV RdRp and HEL1 domains were postulated to play a central role in RNA synthesis. These domains, along with 3CLpro, were found to possess unique structural properties (Gorbalenya et al. 1988, 1989). RdRp has a replacement of Gly by Ser in the GDD signature that is otherwise absolutely conserved in positive-strand RNA viruses. The substitution of this Gly residue was later found to be a common feature of all nidoviruses. HEL1 is uniquely associated with ZF in the same protein and evidence for an important role of the ZF domain in HEL1 activity and other functions has emerged (van Dinten et al. 2000; Seybert et al. 2005). Nidovirus 3CLpro has several unique features (Barrette-Ng et al. 2002; Anand et al. 2002) and the two flanking hydrophobic domains have not been observed elsewhere. Furthermore, these and other (nidovirus-specific) conserved domains are positioned in a very specific and unique order within the replicase. Taken together, these observations confirmed that coronaviruses were the prototype of a separate supergroup (an informal rank above the family level) of positive-strand RNA viruses.

Since most unique features of the proposed IBV replicase organization were derived from the analysis of weak sequence similarities, independent validation of these findings was important and became possible upon publication of the sequence of MHV (Bredenbeek et al. 1990; Gorbalenya et al. 1991; Lee et al. 1991; Bonilla et al. 1994). These analyses confirmed and extended the predictions made for IBV and also revealed that the most N-terminal ~2 000 amino acids of the replicase are poorly conserved between coronaviruses. Among the few conserved features identified in this region were the so-called X domain and two papainlike proteinase (PLpro) domains (Gorbalenya et al. 1991) that are part of the same protein (nsp3) (see Figure 2). The X

domain was shown to be a homologue of a functionally uncharacterized domain previously identified in the vicinity of the HEL1 domain in replicative polyproteins of the *Togaviridae* (Dominguez et al. 1990). It was subsequently shown to be a unique property of PLpros to contain a homologue of the Zn-ribbon domain that is commonly associated with a cellular transcription elongation factor (Herold et al. 1999). The presence of this Zn-ribbon, which is essential for the proteolytic activity of PLpro, implies a role in RNA synthesis for the nsp3 protein that contains this domain.

Further insight into the organization and evolution of coronavirus replicative polyproteins was gained by a study of the equine torovirus EToV (Berne virus) (Snijder et al. 1990a), which was found to have a coronaviruslike genome organization, including the characteristic RdRp–ZF–HEL1 domains encoded by ORF1b and a frameshifting signal at the ORF1a/1b junction. These results unequivocally established the relationship between toroviruses and coronaviruses, even though these viruses have different virion morphologies. The comparison also led to new assignments. In the C-terminal part of the ORF1b-encoded protein, a unique conserved domain of unknown function was delineated (Snijder et al. 1990a). Secondly, a surprising similarity was found between the C-terminal region of EToV pp1a and an accessory protein encoded by ORF2 in group 2 coronaviruses such as MHV (Snijder et al. 1991). This observation indicated that some replicative proteins are optional (since they are not conserved in all corona- and toroviruses) and that they can be subject to reshuffling, possibly through RNA recombination.

In 1991, the publication of the first complete arterivirus sequence, that of EAV, revealed several remarkable features of this virus group (den Boon et al. 1991). At that time, this virus, together with alphaviruses and rubiviruses, was considered to be part of the *Togaviridae* family. Although EAV has distinct virion morphology and a genome size approximately half that of an average coronavirus genome, it proved to share numerous features with coronaviruses. In particular, the ORF1b-encoded polyprotein, expressed through ribosomal frameshifting, contained distant homologues of the four previously identified conserved domains in corona- and toroviruses. Likewise, the pp1a polyprotein contained a characteristic domain set consisting of PLpro domains, as well as a 3CLpro domain embedded between two hydrophobic domains (den Boon et al. 1991).

However, at the same time, arteriviruses were also found to possess specific features. All conserved arterivirus domains were found to be smaller than their coronavirus counterparts, and the sequence similarities between ORF1a-encoded sequences of corona- and arteriviruses were so weak that a relationship could not be rigorously established (Ziebuhr et al. 2000). Unlike their coronavirus counterparts and the related picornavirus enzymes, the arterivirus 3CLpro was shown to employ Ser as the catalytic nucleophile (Snijder et al. 1996; Barrette-Ng et al. 2002). Importantly, though, the replicase domains of arteriviruses, like those of the corona- and toroviruses, were found to have no strong sequence similarities to other virus groups. All these observations were most compatible with a pronounced divergent evolution of arteriviruses and coronaviruses from a common ancestor (den Boon et al. 1991). Accordingly, these families were united in a coronavirus-like supergroup (Gorbalenya and Koonin 1993; Snijder and Horzinek 1993), which was subsequently recognized as the order *Nidovirales* (Cavanagh 1997).

The most recent, and most unexpected, extension of the nidovirus order was triggered by the sequence analysis of RNA viruses infecting prawns in Australia and Southeast Asia, GAV and Yellow head virus (YFV). The phylogenetic relationship between GAV and nidoviruses became evident from comparative sequence analyses of the replicase polyproteins, which again revealed striking similarities in organization and mode of expression (Cowley et al. 2000). Comparative sequence analysis identified ORF1b-encoded putative helicase and RdRp domains, ordered as in other nidoviruses and carrying specific sequence signatures, such as the GDD to SDD replacement in the RdRp. Collectively, the data argued that the replicases of GAV (infecting invertebrates) and other nidoviruses (infecting vertebrates) have a common ancestor. On the other hand, the presence of a number of regions with low sequence similarity in the ORF1b-encoded sequence and, in particular, the extremely poor pp1a conservation also suggested that GAV has diverged significantly from the vertebrate nidoviruses. Indeed, the only region in pp1a with significant sequence similarity proved to be a 3CLpro domain, again flanked by hydrophobic (probably membrane-spanning) domains (Ziebuhr et al. 2003).

Finally, the impulse given to the analysis of the nidovirus replicase by the SARS outbreak of 2003 should be mentioned. The relatively distant position of the SARS-coronavirus (SARS-CoV) among previously identified coronaviruses, and the impact of the disease that it causes, resulted in renewed in-depth analyses of all genes and proteins of coronaviruses (Rota et al. 2003; Marra et al. 2003; Thiel et al. 2003; Snijder et al. 2003; Stadler et al. 2003; Yan et al. 2003; Ziebuhr 2004b). At the level of the replicase, distant relationships between cellular enzymes involved in RNA metabolism and five nidovirus domains were tentatively identified (Snijder et al. 2003; von Grotthuss et al., 2003; Yan et al. 2003) and partially verified by subsequent experimental analysis (Ivanov et al. 2004; Bhardwaj et al. 2004). Thus, it was proposed that adenosine diphosphate-ribose1″-phosphatase (ADRP) activity is associated with the coronavirus X-domain (Gorbalenya et al. 1991) and cyclic phosphodiesterase (CPD) activity with the domain found at the C-terminal region of pp1a in EToV and in the ORF2 protein of group 2 coronaviruses (Snijder et al.

1991). New functional assignments were also made for an array of domains conserved in the carboxyl-terminal region of pp1ab (now named nsp14, 15, and 16 in coronaviruses) that is comprised of a 3′-to-5′ exonuclease (ExoN), a uridylate-specific endoribonuclease (NendoU), and an *S*-adenosylmethionine-dependent ribose 2′-*O*-methyltransferase (2′-*O*-MT). These three domains are conserved in coronaviruses, toroviruses, and roniviruses, but only the NendoU domain is present in arteriviruses. It was proposed that these five nidovirus enzymes might cooperate in a manner described for their cellular homologues. In this cooperation NendoU, ExoN, and 2′-*O*-MT might provide specificity and the CPD and ADRP may modulate the pace of the reaction(s) in a single or several pathways. The expected functional hierarchy of the five nidovirus enzymes may be reflected in their level of evolutionary conservation, with the most conserved NendoU playing a key role in the initiation of a cascade of reactions (Snijder et al. 2003).

In summary, the comparison of nidovirus replicases leads to the conclusion that the basis of nidovirus common ancestry lies in the enzymatic functions that drive virus replication. Comparative analysis of pp1a and pp1ab (particularly between coronaviruses and arteriviruses) reveals a remarkable colinearity in organization, which contrasts with the overall low sequence similarity and size difference. As our understanding of the genetic blueprints for the different nidovirus branches continues to be refined, novel details of the nidovirus-specific replication machinery are coming to light. Despite many overall similarities, the enormous evolutionary distance between the different groups united in the order *Nidovirales* guarantees that many minor and possibly also major differences will emerge during the coming years. Advanced bioinformatics, structural studies, biochemistry, virus genetics, and molecular virology each play a specific and valuable role during the functional dissection of this unique positive-strand RNA virus replicase.

SUBGENOMIC RNA SYNTHESIS

The synthesis of one or multiple subgenomic mRNAs is a mechanism that many positive-strand RNA viruses have evolved to selectively express structural and accessory proteins from ORFs other than those encoding the major replicase subunits (reviewed in Miller and Koev (2000)). In nidoviruses, these ORFs are located downstream of the replicase ORFs 1a and 1b. Accordingly, nidovirus RNA synthesis also entails, in addition to the replication of the full-length genome, the production of a set of subgenomic mRNAs. The nidovirus genome and subgenomic mRNAs form a 3′ co-terminal nested set of three to 10 mRNAs, depending on the particular virus species. The 5′-proximal part of each subgenomic mRNA encompasses a specific ORF (or sometimes several ORFs) from the 3′-proximal genome region, which thus becomes accessible for translation by host ribosomes.

For a long time, it was thought that the hallmark of nidoviruses (mostly coronaviruses at that time) was the fact that the viral subgenomic mRNAs are composed of regions that are noncontiguous in the viral genome (Spaan et al. 1983; Baric et al. 1983; Lai et al. 1984). All subgenomic mRNAs of coronaviruses, and later also arteriviruses (de Vries et al. 1990), were found to carry a common 5′ leader sequence, which is a copy of the 5′-terminal sequences of the genomic RNA. Thus, these subgenomic mRNAs (and the genome) share both 5′- and 3′-terminal sequences. In some respects, their mosaic nature resembles that of eukaryotic mRNAs generated by splicing.

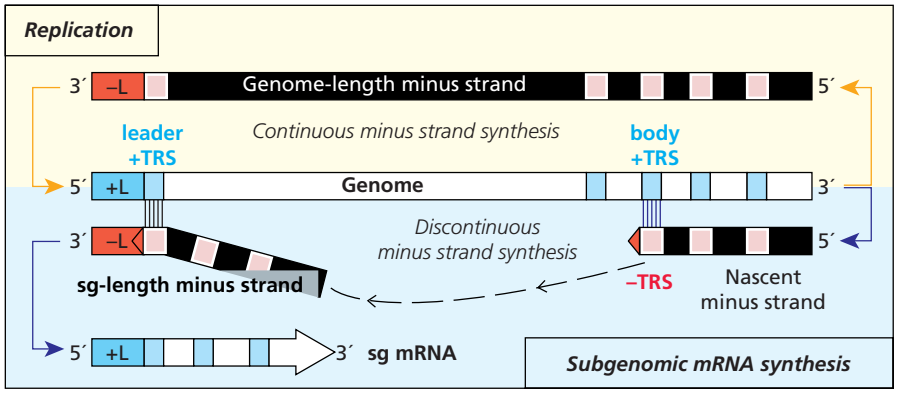
More recently, however, it has become clear that the generation of subgenomic mRNAs containing noncontiguous sequences is not universal amongst the nidoviruses. First, evidence was obtained that makes it unlikely that ronivirus subgenomic mRNAs contain a common leader sequence (Cowley et al. 2002). Shortly afterwards, it was found that only one of the subgenomic mRNAs (RNA 2) of the torovirus EToV shares a short 5′-proximal leader sequence with the genome, whereas the smaller subgenomic mRNAs (like those of roniviruses) do not contain such a common leader sequence (van Vliet et al. 2002). Thus, there are differences in the mechanisms used to generate nidovirus subgenomic mRNAs and more studies are needed to identify the unique aspects of roniviruses and toroviruses RNA synthesis. However, the differences described above, rather than being viewed as fundamental, may transpire to be 'variations on a theme.' Thus, we will describe the discontinuous mode of subgenomic RNA synthesis used by coronaviruses and arteriviruses, which has been studied in much more detail, as a basis for identifying mechanistic principles that, eventually, may be related back to the unique nidovirus replicase functions that have been identified recently.

Despite the similarities between the structure of spliced eukaryotic mRNAs and the subgenomic mRNAs of coronaviruses and arteriviruses, the underlying mechanisms that generate these RNAs probably differ dramatically. The coronavirus/arterivirus subgenomic RNAs are generated in the cytoplasm of the infected cell via a unique mechanism that does not involve the post-transcriptional processing of a larger precursor to convert it into a smaller mature product (Jacobs et al. 1981; den Boon et al. 1995b; Yokomori et al. 1992), as is the case with host mRNAs generated by splicing (a nuclear process). Rather, nidovirus subgenomic RNAs derive from a process of discontinuous RNA synthesis that appears to be a variant of the similarity-assisted RNA recombination that can operate during genome replication (for a review, see Nagy and Simon (1997)).

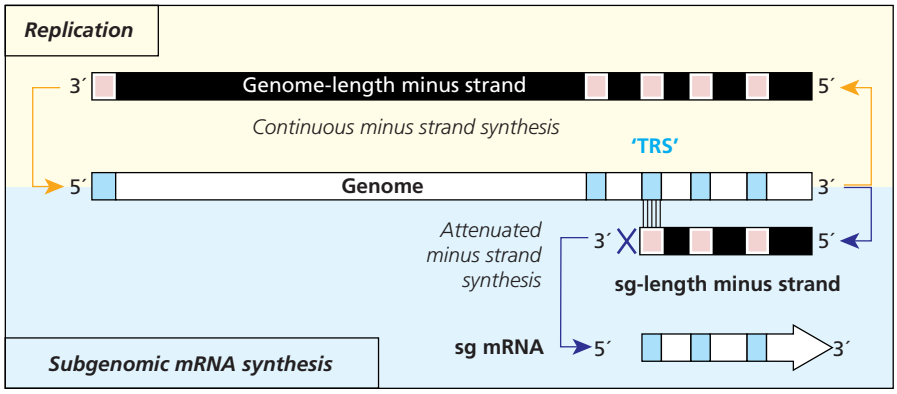
Over the years, different models have been proposed to explain the discontinuous step in arterivirus and

coronavirus subgenomic RNA synthesis (reviewed in van der Most and Spaan (1995), Brian and Spaan (1997), Lai and Cavanagh (1997), Snijder and Meulenberg (1998, 2001), Lai and Holmes (2001)). In the two most prominent models (commonly referred to as 'leader-primed transcription' and 'discontinuous minus strand synthesis', see Figure 4), it is proposed that short conserved transcription-regulating sequences (TRS) play a key role in connecting the common leader sequence to each of the subgenomic RNA 'bodies' (the variable part of the mRNA that is identical to a part of the 3′-proximal region of the genome). These TRS elements are present at the 3′ end of the leader (leader TRS) and at the 5′ end of each of the regions in the genome that corresponds to a subgenomic RNA body (body TRSs). In the subgenomic RNA, a copy of the TRS connects the leader and body regions that are noncontiguous in the genome. Base-pairing between the leader TRS (+TRS) (in the genome) and the complement of the body TRSs (−TRS) (in the nascent minus strand) was shown to be essential for subgenomic mRNA synthesis (van Marle et al. 1999; Pasternak et al. 2001, 2003; Zuniga et al. 2004; Curtis et al. 2004).

According to the 'leader-primed transcription' model, subgenomic RNA synthesis would be primed by free leader molecules whose +TRS would base-pair with one of the body TRS complements in the anti-genome. Subsequently, using the anti-genome template, the leader primer would be extended with the body part to complete the subgenomic mRNA (Spaan et al. 1983;



(a)



(b)

Figure 4 *Models for subgenomic mRNA synthesis from minus-strand subgenome-length templates in different nidoviruses.* **(a)** *Model for coronaviruses and arteriviruses, which have a common 5′ leader sequence on all viral mRNAs. Discontinuous extension of minus-strand RNA synthesis (Sawicki and Sawicki 1995) has been proposed as the mechanism to produce subgenome-length minus-strand templates for subgenomic mRNA synthesis. Obviously, minus-strand RNA synthesis can also be continuous (top), yielding the genome-length minus-strand required for replication. During discontinuous minus-strand synthesis (bottom), the replicase/transcriptase is proposed to be attenuated at one of the body TRSs in the 3′-proximal part of the genome. Subsequently, the nascent minus strand, with the complement of the body TRS at its 3′ end, is redirected to the 5′-proximal part of the template, where its 3′ end can base-pair with the complementary leader TRS. Next, the subgenome-length minus-strand is completed by extension with the antileader sequence and used as template for mRNA synthesis.* **(b)** *Ronivirus subgenomic mRNAs and all but the largest subgenomic mRNAs of toroviruses do not contain a common 5′ leader sequence (Cowley et al. 2002; van Vliet et al. 2002), although conserved ('body TRS-like') sequences are found upstream of each of the genes in the 3′ proximal part of their genome. It is thought that these viruses may employ a variant of the mechanism explained in* **(a)**, *in which attenuation of minus-strand RNA synthesis does occur, but the discontinuous step required for antileader addition does not take place. Rather, the attenuated minus-strand RNA can serve directly as template for subgenomic mRNA production.*

Baric et al. 1983; Lai et al. 1984). This model was partly based on the fact that complements of subgenomic RNAs (subgenome-length minus strands) were initially not detected in cells infected with MHV (Lai et al. 1982). However, after the subsequent discovery of such molecules in coronavirus- and arterivirus-infected cells (Sethna et al. 1989; Sawicki and Sawicki 1990; den Boon et al. 1996), an alternative model for subgenomic mRNA synthesis was proposed (Figure 4a) (Sawicki and Sawicki 1995). According to this model, the discontinuous step in subgenomic RNA synthesis does not occur during plus, but during minus-strand RNA synthesis. The body TRSs in the plus-strand template would attenuate minus-strand synthesis, after which the nascent minus strand, having a TRS complement at its 3′ end, would be transferred to base-pair with the leader TRS, which may be presented as part of a stem–loop structure (Chang et al. 1996; van Marle et al. 1999; van den Born et al. 2004). The subgenome-length minus strands would then be completed by extension with the complement of the leader sequence and subsequently be used as templates for the synthesis of subgenomic mRNAs. In recent years, this model, which was originally proposed by Sawicki and Sawicki, has gained considerable experimental support from both biochemical and genetic studies (Baric and Yount 2000; Sawicki et al. 2001; Pasternak et al. 2001).

The mechanism of discontinuous subgenomic RNA synthesis, as proposed for coronaviruses and arteriviruses, is a unique strategy for the generation of viral subgenomic transcripts. It contrasts with a mechanism used by many other RNA viruses that have been found to produce subgenomic mRNAs by internal initiation of transcription from 'promoters' in the antigenome (Miller et al. 1985). However, the mechanism used by coronaviruses and arteriviruses may share similarities with that of other positive-strand RNA viruses that employ premature termination (attenuation) of minus-strand RNA synthesis (reviewed in White (2002)). Also in the latter case, subgenome-length minus strands are produced that serve as the templates for subgenomic mRNA synthesis, but their synthesis does not involve the discontinuous extension of the nascent minus-strand RNA.

One of the most interesting questions that remains to be resolved is whether attenuation of minus-strand RNA synthesis is used by roniviruses and toroviruses (van Vliet et al. 2002). This property might explain the conservation in torovirus (Snijder et al. 1990b; van Vliet et al. 2002) and ronivirus (Cowley et al. 2002) genomes of sequences that appear to be the equivalent of the body TRSs of coronaviruses and arteriviruses. Whereas in coronaviruses and arteriviruses the attenuation step would be followed, according to the model of Sawicki and Sawicki, by extension of the nascent minus strand with the antileader sequence, the attenuated minus-strand products of roniviruses and toroviruses may be directly used as templates for subgenomic mRNA synthesis (Figure 4b). Thus, attenuation of minus-strand RNA synthesis may be the common feature that unites the mechanisms used to produce subgenomic mRNAs in different nidoviruses, while the process of discontinuous RNA synthesis may be restricted to coronaviruses and arteriviruses. This conclusion provokes, of course, the question of the functions of the coronavirus and arterivirus common leader sequence at the level of, for example, regulation of RNA synthesis and mRNA translation and, obviously, of alternative mechanisms used by nidoviruses that generate mRNAs that lack a common leader sequence.

NIDOVIRUS EVOLUTION

Comparative genomics and the phylogenetic analysis of nidovirus replicative domains clearly established nidoviruses as a distinct evolutionary lineage among positive-strand RNA viruses. The main nidovirus branches have diverged profoundly from each other in the course of evolution. This is evident from the enormous diversity among nidovirus enzymes, which exceeds that of their cellular homologues. For instance, nidovirus main proteinases have evolved several variants of the most conserved part of the enzyme (Gorbalenya et al. 1989; den Boon et al. 1991; Anand et al. 2002; Barrette-Ng et al. 2002; Ziebuhr et al. 2003). In nidovirus proteinases, the otherwise uniform catalytic site may include either a serine or a cysteine nucleophile and other structural variations not encountered in the cellular homologues that were identified in the three main kingdoms of life. Low replicase fidelity and, in particular, a high frequency of RNA recombination have been implicated in the generation of the nidovirus diversity. To achieve this diversity in the restricted and relatively slowly evolving environment of the infected host cell, these mechanisms must have been at work over a considerable period of time, possibly many millions of years (Koonin and Gorbalenya 1989). Given the considerable diversity of the conserved replicase among nidoviruses, it may not be surprising to see that three families of nidoviruses employ seemingly unrelated sets of structural protein genes that evolve faster than the replicases of the same origin. It has been hypothesized that a major split in nidovirus evolution, giving rise to viruses with remarkably different genome sizes, may have been coupled with the acquisition of different nucleocapsid protein genes by corona- and arteriviruses (Godeny et al. 1993).

How did the nidovirus genetic plan come to life? How have nidoviruses evolved replicative polyproteins of such outstanding complexity? There are two basic ways to increase complexity – either by acquiring domains from an outside source or by duplication of a pre-existing domain of the parental genome. These processes depend on intergenomic and intragenomic recombination, respectively. For example, most nidoviruses encode two

or more papainlike proteinase (PLpro) domains that form family-specific branches that are well separated from their relatives of other origin (Ziebuhr et al. 2000). This implies that an amplification of PLpro domains has contributed to the enlargement of the nidovirus genome (den Boon et al. 1995a; Ziebuhr et al. 2001). However, it remains an open question how many of such events occurred and when they took place – in the ancestral nidovirus lineage or later, in individual nidovirus branches.

The nidovirus-replicative domains show remote sequence similarity with replicative proteins of other (super)groups of positive-strand RNA viruses. In particular, the coronavirus ADRP and nidovirus HEL1 domains cluster with homologues encoded by viruses from the *Alphavirus*-like supergroup (Gorbalenya et al. 1988; Gorbalenya et al. 1991). In contrast, the coronavirus RdRp and main proteinase (3Clpro) domains have specific affinity with homologous enzymes in plant potyviruses (Gorbalenya et al. 1989, 2002) and the coronavirus PLpros may be grouped with the leader proteinase (Lpro) of animal aphthoviruses (Gorbalenya et al. 1991). Both poty- and aphthoviruses belong to the picornavirus-like supergroup. Sequence affinity with the potyvirus 3CLpro was also documented for the ronivirus main proteinase (Cowley et al. 2000; Ziebuhr et al. 2003). Furthermore, and in apparent contradiction to the relationships cited above, the main proteinase of arteriviruses clusters with homologues encoded by plant sobemo- and luteoviruses (Snijder et al. 1996; Ziebuhr et al. 2000). Moreover, all these proteins also have complex, albeit very distant, relationships to a variety of cellular homologues (prototypes).

These mosaic relationships between different groups of positive-strand RNA viruses suggests that their replicative domains are derived from several common gene pools and that their genomes have been built by reshuffling these domains. This hypothesis implies that the nidovirus replicative polyproteins may, in fact, be of chimeric origin. On the other hand, no evidence has been obtained so far that any of the nidovirus-replicative domains is evolutionarily interleaved with related domains of other origin. Thus, it remains possible that all or some of these similarities to members of other virus supergroups have been preserved in the course of a continuous process of profound evolution of positive-strand RNA viruses, including nidoviruses, from a common root (Gorbalenya and Koonin 1993). More analyses and new sequences are needed for a more detailed reconstruction of the evolution of nidovirus genomes in general and the nidovirus replicase gene in particular.

From a practical perspective, the vast genetic diversity of nidoviruses presents the basis for designing molecular probes of different selectivity and constitutes a formidable challenge in the development and application of therapeutics. The first genome-based and immunochemical probes for the detection of multiple and individual nidoviruses have been developed by targeting their most and least conserved components, respectively. The list of functions that are unique and well conserved in the order *Nidovirales* or its separate branches is constantly growing and provides targets for specific drugs. To be effective, these drugs must be able to cope with viruses that have shown an amazing structural plasticity during their evolution.

CHARACTERISTICS OF THE VIRUSES

INTRODUCTION

As their name implies, parvoviruses, from the Latin *parvus* meaning small, are amongst the smallest of the known animal viruses, having nonenveloped icosahedral protein virions approximately 250 Å in diameter. These particles, which comprise only DNA and protein, are quite dense and extremely rugged. They can survive many inactivation procedures, including most used to protect the blood supply, and remain fully viable at ambient temperatures for months or years. Some members of the family are major pathogens of insects and domestic animals, but only one, human parvovirus B19, has so far been identified as a human pathogen, and is the causative agent of fifth disease (erythema infectiosum). Many parvoviruses are essentially apathogenic, and over the past few years this characteristic has helped them gain recognition as effective vectors for the safe delivery of vaccines or therapeutic genes.

In the known biosphere, only parvoviruses have DNA genomes that are both single-stranded and linear. Parvoviruses package a single genomic molecule between 4 and 6 kb in length, which terminates in short palindromic sequences that can fold back on themselves to create duplex hairpin telomeres. These terminal hairpins are essential for the virus's unusual replication strategy, and hence serve as an invariant hallmark of the family. DNA replication proceeds through a series of duplex intermediates in the host cell, via a characteristic unidirectional strand-displacement mechanism called 'rolling-hairpin' synthesis, organized by the major viral nonstructural protein. Transmitted as single-stranded progeny, parvoviruses do not arrive in their host cell with a complementary copy of their genome sequence against which environmental damage can be corrected. This may well contribute to the observation that their genetic mutation rates are higher than those seen in double-stranded DNA viruses, and approach those more commonly associated with some RNA viruses. However, their tendency to drift genetically is held severely in check by the compact nature of the genome, and the structural constraints on its few gene products, which ensure that only a limited spectrum of mutations are compatible with progeny viability.

Parvovirus particles exhibit T = 1 icosahedral symmetry, but are generally constructed from 2–4 capsid protein size classes, usually called VP1 to VP4. Of these, VP1 is the longest, at 80–96 kDa, while the remainder comprise a nested set of polypeptides derived from its carboxy terminus (VP2 64–85 kDa, VP3 60–75 kDa, and VP4 49–52 kDa), with VP2 or VP3 being the principal capsid component. Particles are built up from 60 equivalent copies of this large carboxy-terminal core sequence, and the amino-terminal

extensions carried by some of the polypeptides are alternately concealed or exposed at the particle surface during different stages of the infectious cycle, displaying stage-specific trafficking signals or effector domains. Notably, VP1-specific sequences from most genera contain the enzymatic core of a phospholipase A2 (PLA2) molecule, which is essential for infectious entry and appears to be a unique feature of this family (Zadori et al. 2001). Virions lack essential lipids, and none of the viral proteins are known to be glycosylated, but they are modulated post-translationally by important phosphorylation events. Parvovirus virions are exceptionally stable, and quite simple antigenically. In nature only a single serotype of any particular species is generally found circulating in its host population, and this has led to the use of individual serotype, defined by neutralization of infectivity in cell culture, hemagglutination-inhibition, or specific enzyme-linked immunosorbent assay (ELISA), as the major criterion for taxonomic species demarcation (Tattersall et al. 2005). Just two antigenic sites, defined by mutations that confer resistance to neutralization by monoclonal antibodies, have been identified for canine parvovirus (CPV). Despite their differences in capsid serology, the nonstructural proteins of most species in a genus do show antigenic cross-reactivity, so that genera-specific infections can often be diagnosed serologically.

While adeno-associated viruses (AAV), from the genus *Dependovirus*, generally require coinfection with a helper adenovirus or herpesvirus in order to complete their replication cycle, the great majority of family members are capable of helper-independent, so-called 'autonomous,' replication. Viral genomes typically contain just two gene cassettes, of which one encodes the nonstructural proteins (called Rep in the AAVs and NS in other species), which are essential for viral gene expression and DNA replication, while the other encodes the overlapping set of capsid polypeptides. The limited coding potential of these genomes therefore renders them highly dependent on the synthetic machinery provided by the host cell for their own, preferential, replication. In contrast to most other DNA viruses, parvoviruses do not encode proteins that can coerce resting cells to enter cell division. Nevertheless, they do require host cells to enter S phase in order to provide the extensive deoxynucleotide triphosphate pools and active cellular DNA synthetic apparatus required for their replication, and that are not present in interphase cells. As a consequence, autonomously replicating parvoviruses cannot grow in resting cell populations, and amplify best in populations of rapidly dividing cells, both in vitro and in vivo. This lack of any encoded positive growth regulators means that parvoviruses are universally nontumorigenic, and indeed, for reasons that are not yet clear, they are often specifically oncosuppressive, exhibiting an enhanced ability to replicate in transformed cells.

AAVs overcome their limited gene repertoire by resorting to a pattern of latent infection in which they generally integrate into the host-cell genome, only switching to a productive life cycle when their host cell becomes infected with a 'helper' virus. In this situation, the helper inadvertently activates resident AAV genes, while also reprogramming the host's cell cycle for its own use, sending the cell into S phase. Resulting helper virus replication is paralleled, or even overtaken, by that of the resident AAV, culminating in cell death and the release of infectious progeny of both viruses. In recent years, this capacity of AAV to integrate, or otherwise persist in host cells, has been exploited for the safe and efficient delivery of a wide range of therapeutic genes, so that AAVs are now among the most promising vector systems available for long-term gene substitution or correction strategies. In most of these vectors all of the viral genes are deleted to accommodate the therapeutic transgene, so that these constructs cannot give rise to infectious progeny.

Characteristics of the viral life cycle inevitably dictate the types of disease parvoviruses are able to induce. On one hand, AAVs have been selected for their ability to remain essentially invisible over prolonged periods of time, and to specifically exploit coinfection with potentially tumorigenic helper viruses, while the helper-independent viruses require cells of specific differentiated phenotypes which must also be undergoing cell division, and hence DNA replication, of their own volition. These viruses are therefore parasites of specific, rapidly dividing cell populations, and generally only give rise to overt disease in situations where large numbers of their target cells continue to replicate in the adult, or where the timing of organ development in the fetus means that transiently replicating cell populations, once damaged, can no longer be effectively regenerated, resulting in fetal or neonatal death, or teratogenesis. In healthy adults, the immune response mounted against otherwise innocuous viruses can also sometimes exacerbate the pathogenesis of infection, as manifest, for instance, by the rashes and polyarthropathy which often follow infection of otherwise healthy people by human parvovirus B19.

HISTORY AND TAXONOMIC RELATIONSHIPS WITHIN THE FAMILY *PARVOVIRIDAE*

In 1970 the taxonomic family, *Parvoviridae*, was established to encompass all small nonenveloped viruses with approximately 5 kb linear, self-priming, single-stranded DNA genomes. Although genome sequences were not then available to confirm their phylogenetic relationships, the DNA sequence data amassed since that time confirm that all viruses in the family share a common evolutionary history. As delineated in Table 1, the family *Parvoviridae* is currently divided into two subfamilies on the basis of host range: the *Parvovirinae*,

Table 1 *Taxonomic structure of the family* Parvoviridae

Subfamily *Parvovirinae*	Subfamily *Densovirinae*
Genus	Genus
Parvovirus	*Densovirus*
Erythrovirus	*Iteravirus*
Dependovirus	*Brevidensovirus*
Amdovirus	*Pefudensovirus*
Bocavirus	

which infect vertebrate hosts, and the *Densovirinae*, infecting insects and other arthropods (Tattersall et al. 2005). This chapter will focus exclusively on members of the *Parvovirinae* subfamily. These are currently divided into five genera, as detailed in the phylogenetic tree in Figure 1, but we will mostly consider the properties of species belonging to the three major genera, namely the dependoviruses, predominantly the helper-dependent AAVs, and the autonomously replicating parvoviruses and erythroviruses. The latter include the human pathogen, parvovirus B19, and are named for the striking tropism of this agent for cells of the erythroid lineage.

The genus *Parvovirus*

In 1959, a small stable virus, subsequently named *Kilham rat virus* (KRV), was isolated from lysates of an experimental rat tumor (Kilham and Olivier 1959). In the following decade a number of other physically similar agents were identified as contaminants of laboratory tumors that were being serially transplanted in normal or immunosuppressed rodents, and as contaminants of cell cultures or other virus stocks in routine laboratory use (Tattersall and Cotmore 1986). Although lacking known host species, some of these isolates were injected into rodents where they caused a broad spectrum of pathology, which varied with the virus serotype and age of the host, from apparently asymptomatic viremia to teratogenesis and fetal or neonatal death (Toolan 1961). Concurrently, an infectious agent responsible for epidemics of enteritis, panleukopenia, and congenital cerebellar ataxia in domestic cats was identified, called *Feline panleukopenia virus* (FPV), and it soon became apparent that this shared the same characteristic size and genome structure as the so-called 'rodent' parvoviruses isolated in the laboratory (Kilham et al. 1967; Gorham et al. 1966). Transplacental transmission has been described for several viruses in the genus, and under experimental conditions their host range can often be extended to include a large number of vertebrate species. Since the capsids of most species hemagglutinate red blood cells of one or other mammalian species, this provides a facile assay for virion detection and quantitation. These viruses, listed in Table 2, are now all classified in the genus *Parvovirus*, with the murine virus, *Minute virus of mice* (MVM) (occasionally referred to as *Mice minute virus* (MMV)), as the type species.

Much of our knowledge of the whole parvovirus family, and the nature of parvoviral infections, has been derived from the study of these autonomously replicating viruses, which generally grow efficiently in cell culture and are readily susceptible to experimental manipulation. Mature virions of most species in the genus contain DNA strands that are predominantly negative-sense with respect to transcription, while one virus, LuIII, packages approximately equimolar positive and negative-sense strands. This unusual variability is less significant than at first suspected, since it is caused by differential rates of initiation from the two viral replication origins, rather than by any strand-specific packaging signal or mechanism. The linear single-stranded DNA genome, 5.0–5.3 kb in length, has hairpin structures at both the 5′ and 3′ ends. However, the 3′-terminal, or left-end, hairpin is 121 nucleotides (nt) in length, while the 5′, or right-end, structure is 248 nts long, and the left- and right-end hairpins are quite different from one another, both in sequence and predicted secondary structure. The intervening single-stranded region of the genome contains two mRNA transcription units, with promoters at map units 4 and 38 (where map units represent 1 percent segments of the genome, starting from the left-hand end) and a single functional polyadenylation site, located close to the right-hand end.

The genus *Dependovirus*

The mid-1960s also saw the discovery of a group of physically similar, but defective viruses, which were dubbed 'adeno-associated viruses' because they were common contaminants of laboratory adenovirus stocks. Populations of mature dependovirus virions contain equivalent numbers of positive and negative-sense single DNA strands, each approximately 4.7 kb in length, packaged into separate virions. The genome has three mRNA promoters, at map units 5, 19, 40, and inverted terminal repeats (ITR) of 145 nts, of which the first 125 nts form an imperfect palindrome that folds to create the hairpin-like telomeres. To date, no AAVs have been associated with disease, although they appear to be ubiquitously infectious in humans and primates, and are commonly isolated from adenovirus-infected tissues. At the time of writing, nine distinct full-length AAV genomes have been sequenced (Table 1), but this number is likely to expand rapidly as more potential host species are examined. The best characterized *Dependovirus* is the type species, AAV2, but AAV1, AAV2, AAV3, and AAV4 are extensively homologous at the DNA level. While AAV serotypes 2 and 3 have frequently been isolated from humans, serotypes 1 and 4 are simian isolates, and AAV6 appears to be a recombinant between AAV1 and

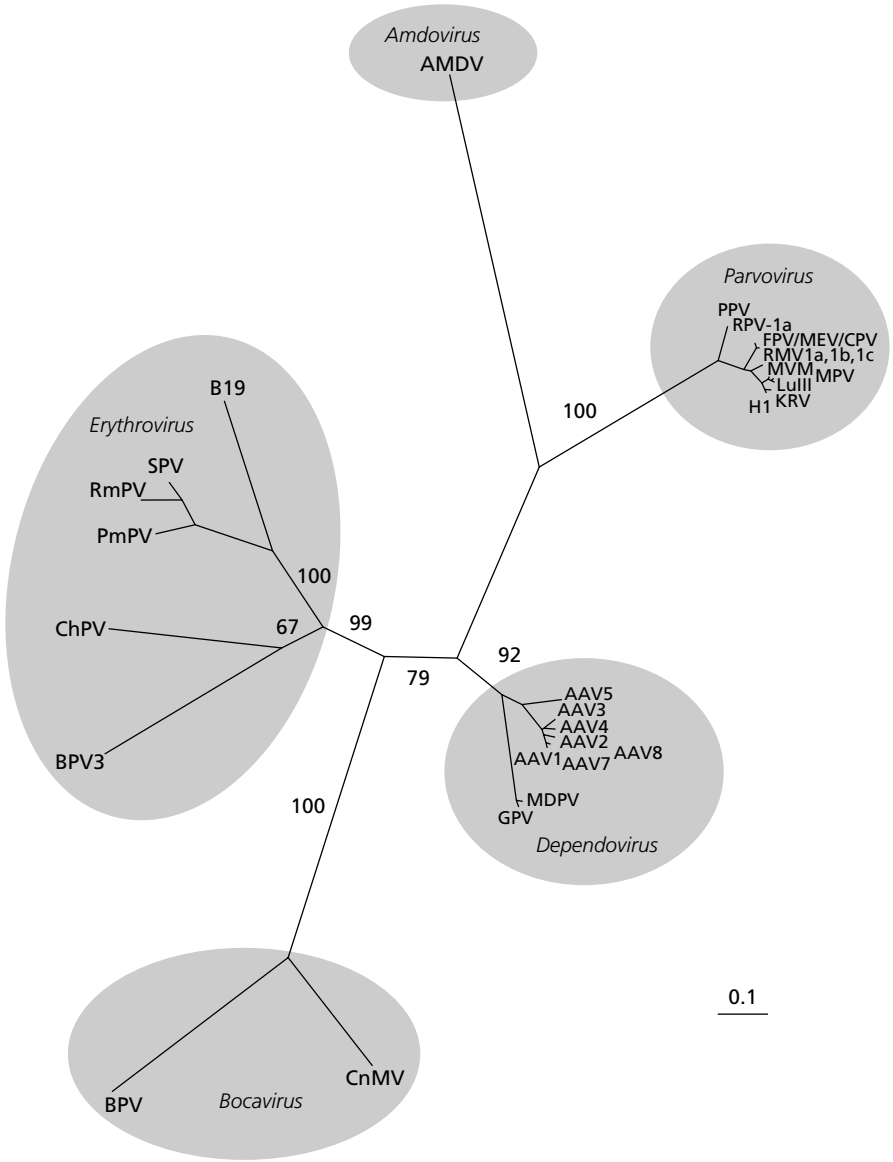

Figure 1 *Phylogenetic relationship between the nonstructural genes of members of the subfamily* Parvovirinae. *The tree was constructed with programs included in the Phylip package (courtesy of Z. Zadori and P. Tijssen).*

AAV2, and is now regarded as a strain of AAV1, since it is specifically neutralized by AAV1-specific antiserum. AAV5 is somewhat less related and has only been isolated once, from humans, where it appears to circulate in conjunction with a herpesvirus helper. Two further closely-related but distinct serotypes, AAV7 and AAV8, were recently isolated from monkeys, and more disparate avian (AAAV) and snake (SAAV) isolates have also recently been cloned and sequenced. For these viruses, efficient replication is dependent upon helper adenoviruses or herpes viruses, both in vitro, and by serological correlation, in vivo. However, in vitro, under certain conditions such as exposure to genotoxic agents or the synchronization of cell replication with hydroxyurea, AAV growth can be detected in the absence of helper viruses.

Originally, as the name *Dependovirus* implies, the genus comprised only helper-dependent viruses, but phylogenetic analysis, as illustrated in Figure 1, now places the autonomously replicating *Duck parvovirus* and *Goose parvovirus* (GPV) firmly within this genus. The *Duck parvovirus* species currently comprises two closely related strains, Muscovy duck parvovirus (MDPV) and Barbarie duck parvovirus (BDPV). These avian parvovirus species also have much larger ITRs, of between 444 and 457 nts, than those of the AAVs. They also differ from the AAVs in exhibiting marked pathogenicity in their natural hosts. The epidemics they cause in commercial flocks of domestic fowl led to their initial identification, in Hungary, where the diseases they elicit have significant agricultural impact.

Table 2 *Members of the subfamily* Parvovirinae

Species	Acronym
Genus *Parvovirus*	
Minute virus of mice	(MVM)
Feline panleukopenia virus strains:	
Feline parvovirus	(FPV)
Canine parvovirus	(CPV)
Mink enteritis virus	(MEV)
Raccoon parvovirus	(RPV)
Hamster parvovirus	(HaPV)
H-1 parvovirus	(H-1PV)
Kilham rat virus strains:	
Kilham Rat virus	(KRV)
H-3 virus	(H-3V)
LuIII virus	(LuIIIV)
Mouse parvovirus 1	(MPV-1)
Porcine parvovirus	(PPV)
Rat minute virus 1	(RMV-1)
Rat parvovirus 1	(RPV-1)
Genus *Dependovirus*	
Adeno-associated virus 1 strains:	
Adeno-associated virus 1	(AAV-1)
Adeno-associated virus 6	(AAV-6)
Adeno-associated virus 2	(AAV-2)
Adeno-associated virus 3	(AAV-3)
Adeno-associated virus 4	(AAV-4)
Adeno-associated virus 5	(AAV-5)
Adeno-associated virus 7	(AAV-7)
Adeno-associated virus 8	(AAV-8)
Avian adeno-associated virus	(AAAV)
Serpentine adeno-associated virus	(SAAV)
Bovine parvovirus 2	(BPV-2)
Duck parvovirus strains:	
Barbarie duck parvovirus	(BDPV)
Muscovy duck parvovirus	(MDPV)
Goose parvovirus	(GPV)
Genus *Erythrovirus*	
Human parvovirus B19 strains:	(B19V)
B19-Au, B19-Wi, B19-A6, B19-LaLi, and B19-V9	
Simian parvovirus	(SPV)
Pig-tailed macaque parvovirus	(PmPV)
Rhesus macaque parvovirus	(RmPV)
Bovine parvovirus type 3	(BPV-3)
Chipmunk parvovirus	(ChpPV)
Genus *Amdovirus*	
Aleutian mink disease virus strains:	(AMDV)
ADV-G (Gorham)	(ADV-G)
ADV-Utah	(ADV-U)
ADV-Pullman	(ADV-P)
Genus *Bocavirus*	
Bovine parvovirus 1	(BPV)
Canine minute virus	(CnMV)

The genus *Erythrovirus*

Human parvovirus B19, the only known human pathogenic member of the *Parvoviridae*, was discovered serendipitously in 1975 as an antigen present in a serum sample bearing the laboratory code 'B19,' from an apparently healthy donor whose blood was being screened for hepatitis reactivity (Cossart et al. 1975). Electron microscopy revealed that the antigen was associated with a virus particle of approximately 23 nm diameter, and the isolate was initially described as 'parvovirus-like' merely because of its size and appearance. Although around 60 percent of normal adults were subsequently found to have antibody to B19 virus (Cohen et al. 1983), suggesting common childhood exposure, the infection was initially thought to be asymptomatic. However, 5 years later the same antigen was identified in the blood of two soldiers suffering from mild fever, and in the next year a survey of sera archived at King's College Hospital, London, suggested an etiologic role for the virus in a type of transient aplastic crisis experienced by children with sickle cell anemia (Pattison et al. 1981). B19 virus has since been shown to be responsible for transient aplastic crisis in patients with a variety of hemolytic anemias. In 1983, the virus was linked sero-epidemiologically to erythema infectiosum (EI), a widespread childhood rashlike disease also referred to as fifth disease (Anderson et al. 1983), and in the next year it was shown that intrauterine transmission of B19 from an infected mother could sometimes lead to hydrops fetalis, particularly in the second trimester of pregnancy. By 1984, the B19 genome had been characterized, cloned, and sequenced (Summers et al. 1983; Cotmore and Tattersall 1984; Shade et al. 1986), allowing it to be placed firmly in the subfamily *Parvovirinae*. However, these analyses revealed that B19 was phylogenetically distant from viruses in the two existing genera (Dependovirus and Parvovirus), so that soon afterward the new genus Erythrovirus was created, with B19 virus as its type species. Populations of mature B19 virions contain equal numbers of positive and negative sense DNA strands of around 5.5 kb, with inverted terminal repeats of 383 nts in which the first 365 nts are palindromic and fold into complex hairpin telomeres. To date this virus cannot be efficiently propagated in any established cell line, so that virus stocks have predominantly been isolated from viremic human sera. Productive infection does occur in some primary erythroid progenitor cells present in primary human bone marrow explants stimulated with erythropoietin (EPO), which has allowed some aspects of the molecular biology of the virus to be studied, and recently an infectious clone of the viral genome was created in a bacterial plasmid (Zhi et al. 2004). This gives rise to limited progeny virus after transfection into the EPO-stimulated erythroid cells, allowing hope for

future rapid advances in the genetic dissection of viral gene products and synthetic processes.

Additional erythroviruses have also been identified in other primate species (listed in Table 2), and these viruses appear to share the exquisite tissue specificity of B19 for erythroid progenitor cells and accordingly give rise to similar disease spectra (O'Sullivan et al. 1994; Green et al. 2000). Subsequently, a more distantly related virus was isolated from Manchurian chipmunks (Yoo et al. 1999), and while this could potentially provide a useful, nonprimate, model system for studying erythrovirus infection, currently little is known about this virus. Recent advances in viral diagnostics using polymerase chain reaction (PCR) technology have also allowed the identification of related viral sequences in sera from healthy bovines, suggesting that these animals likely harbor another apathogenic or weakly pathogenic erythrovirus species (Allander et al. 2001).

The *Amdovirus* and *Bocavirus* genera

Recently the taxonomy of the *Parvoviridae* has been rationalized to more closely reflect their phylogeny by clustering viruses according to the similarity of the gene sequences of their encoded proteins. As shown in Figure 1, this has led to the reapportioning of some disparate autonomously replicating viruses from the genus *Parvovirus* into two new genera: the *Amdoviruses*, containing a single outlying species, *Aleutian mink disease virus* (AMDV); and the *Bocaviruses*, which currently has two members, *Bovine parvovirus* (BPV) and *Canine minute virus* (CnMV). Despite their phylogenetic isolation, most features of these viruses are shared with members of the genus *Parvovirus*. Mature AMDV virions contain a negative-strand DNA of 4 748 nts, with different palindromic sequences at each terminus. Permissive replication is observed in cell culture for only one isolate, ADV-G, which replicates in Crandell feline kidney cells, although restricted replication is also observed in cells bearing Fc receptors, such as macrophages, where the virus's ability to infect may be antibody-dependent (Dworak et al. 1997). There are several highly pathogenic strains of AMDV, and evidence of infection with this virus has been detected in most mustelids, skunks, and raccoons, being of particular economic impact for the mink industry. Virion structure differs slightly from members of the genus *Parvovirus*. Apart from its divergent DNA sequence, the major distinguishing features of AMDV are its VP1 N-terminus, which is much shorter than those of other *Parvovirinae*, and does not contain the phospholipase 2A enzymatic core, and the fact that in vivo its capsid proteins are highly susceptible to proteolysis, so that intact particles contain few full-length polypeptides (Aasted et al. 1984).

The *NS1* and *VP1* genes of the *Bocaviruses*, BPV and CnMV are 34 to 41 percent similar to one another, but their genomes are very distinct from all other viruses in the *Parvovirinae* subfamily. Somewhat larger than other parvoviral genomes, at 5.5 kb, the genomes of *Bocaviruses*, like those of members of the *Parvovirus* and *Amdovirus* genera, have unique termini. BPV is also notable because it packages 90 percent negative-sense and 10 percent positive-sense DNA and because it encodes a 22.5-kDa nuclear phosphoprotein, NP-1, that is distinct from any other parvovirus-encoded polypeptide.

STRUCTURE AND ORGANIZATION OF PARVOVIRUS COMPONENTS

Structure and assembly of the capsid

Parvoviruses elaborate empty capsids and full virions that are nonenveloped, 18–26 nm in diameter, and exhibit T = 1 icosahedral symmetry. The largest capsid polypeptide is routinely designated VP1, the next VP2, and so on, and they constitute a nested set of polypeptides that share a common carboxy-terminal sequence. Sixty copies of this core sequence are assembled to form the particle, with the majority being derived from either VP2 or VP3 polypeptides, but with the VP1 molecules contributing between nine and 12 copies, which are essential for infectivity. The virion has an M_r of about $5.5–6.2 \times 10^6$, with an S_{20w} of 110–122S, and a buoyant density of 1.39–1.43 g/cm^3 in CsCl. The infectious particle comprises between 70 and 80 percent protein, with the remainder being DNA, and mature virions are stable in the presence of lipid solvents, upon exposure to pH 3–9 and, for most species, incubation at 56°C for at least 60 min. The three-dimensional structures of several parvoviruses, namely CPV, FPV, MVM, porcine parvovirus (PPV), AAV2 and galleria mellonella densovirus (*Gm*DNV), have been determined to near atomic resolution by X-ray crystallography. The common core structural feature is an eight-stranded antiparallel β-barrel, a structure shared with many viral structural polypeptides, in which the β-strands are connected by elaborate and highly variable loops that make up most of the viral surface (Chapman and Rossmann 1993). The amino-terminal peptide domains of the larger proteins are submolar, so that their disposition cannot be deduced from X-ray data. Viral genomes are thought to be packaged vectorially in a 3′ to 5′ direction into pre-assembled 'empty' particles, whose X-ray structure appears almost identical to that of the infectious virion. Viral preparations frequently contain large numbers of these empty capsids, which have a density of 1.32 g/cm^3 in CsCl and a sedimentation coefficient of 70S, as well as the 'full,' DNA-containing virions, subgenomic defective DNAs (p = 1.33–1.39 g/cm^3), and particle-assembly intermediates of various densities.

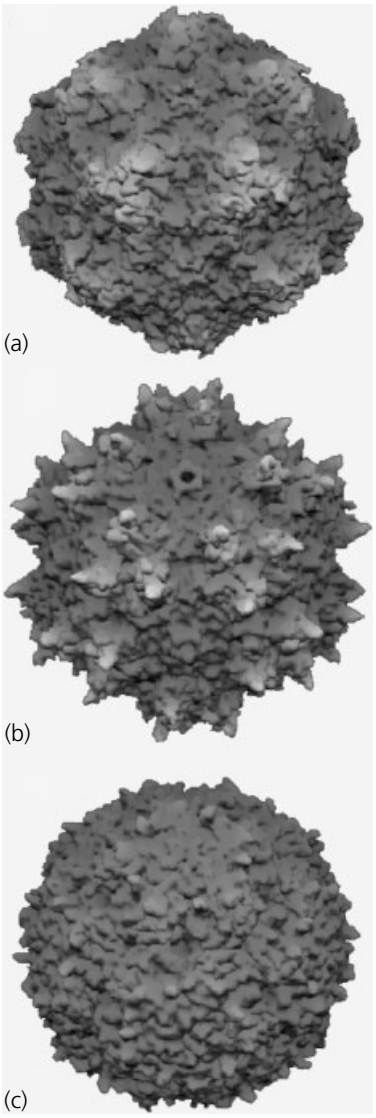

Figure 2 *Space-filling models of the capsid structures of* **(a)** *canine parvovirus (CPV),* **(b)** *adeno-associated virus 2 (AAV-2), and* **(c)** Galleria mellonella *densovirus (*Gm*DNV). Each model is drawn to the same scale and is shaded according to distance from the viral center. In each case, the view is down a two-fold axis at the center of the virus, with three-fold axes left and right of center, and five-fold axes above and below (courtesy of M. Chapman).*

The parvoviral capsid shell displays icosahedral symmetry, but its surface topology can vary substantially between genera, as illustrated in Figure 2 for members of the *Parvovirus*, *Dependovirus*, and *Densovirus* genera. In general, there is an elevated 'spike' surrounding each of the twenty three-fold symmetry axes in the particle, deep depressions at the two-fold axes. A hollow cylindrical structure surrounds each of the 12 icosahedral five-fold axes, which contains a central pore that connects the inside of the virion with the particle exterior. In B19 virus and AMDV, for which there is cryo-electron microscopic imaging and/or low resolution X-ray data, these pores appear occluded, and in full virions of MVM or CPV, from the genus *Parvovirus*, each pore contains a single copy of the glycine-rich, amino-terminus-proximal sequence from a VP2 molecule, positioned so that the amino-terminal 25 amino acids are externalized (Tsao et al. 1991; Agbandje-McKenna et al. 1998). On the outer virion surface these cylindrical structures are themselves encircled by deep canyonlike depressions of unknown function. Neutralizing antibody-binding sites generally map to the three-fold spike, or to its shoulders, and sequences that determine viral host range and oligosaccharide recognition and, in some viruses, receptor binding, lie in the two-fold depression and up the adjacent edge of the three-fold spike. In virions some of the single-stranded DNA also displays icosahedral symmetry, so that about a third of the genome can be visualized, by crystallography, within the particle shell. This DNA is oriented with its bases pointing outwards, forming a number of hydrogen bonds with amino acids of the inner surface of the capsid shell (Xie and Chapman 1996; Agbandje-McKenna et al. 1998).

A single molecule of the viral replication initiator protein (called Rep 68/78 in AAV, but NS1 in most other members of the family) is located on the outside of newly released virions, covalently attached to the extreme 5′ terminus of the genome by a short single-stranded DNA 'tether' sequence which projects through the capsid shell at an unknown location (Cotmore and Tattersall 1989).

Structure of the parvoviral genome

Infectious particles contain a single copy of the linear, nonpermuted, monopartite DNA genome, in which a relatively long single-stranded coding region (approximately 5 kb) is bracketed by short (121–418 nts) palindromic terminal sequences, capable of folding into hairpin duplexes. These duplex viral telomeres, which can be structurally quite complex, are critical for both DNA replication and encapsidation. While they are the essential hallmarks of the parvoviral genome, they vary markedly in size and structure between genera and even between species within the same genus.

With the exception of members of the *Densovirus* and *Pefudensovirus* genera of insect parvoviruses, the viral genome is monosense, that is, it codes for protein only on one strand. On this strand, designated the positive strand, the genes are organized into two separate expression cassettes. By convention, transcription is represented as proceeding left to right on the DNA, placing the 5′ end of the positive strand and the 3′ end of the negative at the left side of the genetic map, as illustrated in Figures 3–5. The open reading frames (ORF) within the left cassette give rise to a small number of nonstructural proteins which are involved in gene

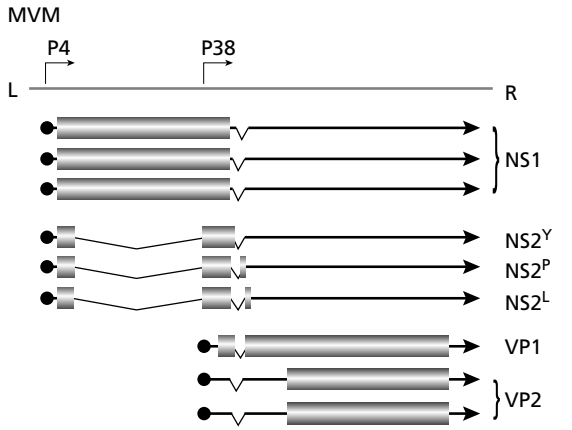

Figure 3 *Gene organization and transcription scheme for members of the* Parvovirus *genus, as shown for* Minute virus of mice *(MVM). Encoded polypeptides are shown as horizontal cylinders. The left ends of the mRNAs (thick lines) are the sites of the mRNA caps (filled circles), the right ends are the polyadenylation sites (arrowheads); introns are indicated by thin carets. Rightward arrows marked with a P indicate the start sites for transcripts driven by promoters whose location is shown in map units from the left-hand end.*

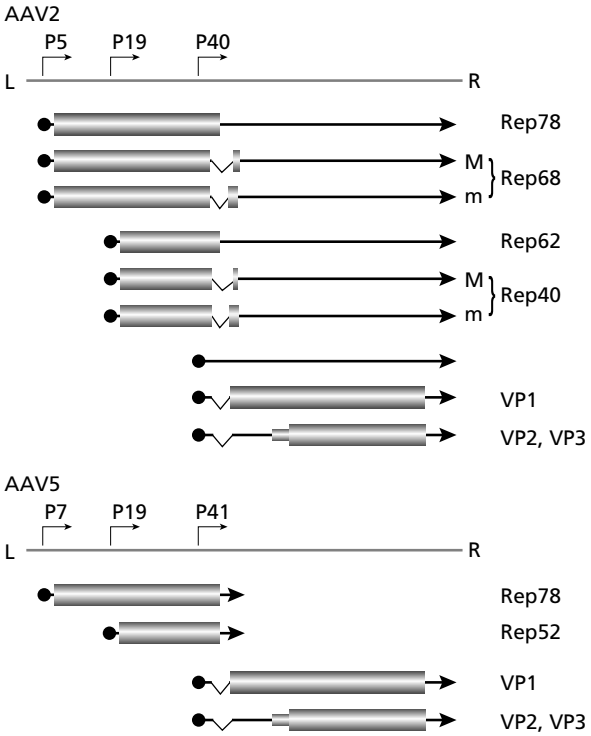

Figure 4 *Gene organization and transcription scheme for members of the* Dependovirus *genus, as shown for adeno-associated virus 2 (AAV-2) (top) and adeno-associated virus 5 (AAV5) (bottom), annotated as described for Figure 3. The narrower cylinder represents the N-terminal region of VP2, translation of which is initiated at a weak, in-frame, ACG start codon.*

regulation and DNA replication, while those encompassed by the right cassette program synthesis of the overlapping set of capsid proteins.

PARVOVIRUS GENOMES

For MVM, the type species of the *Parvovirus* genus, alternate splicing events orchestrate viral gene expression, as shown in Figure 3 (Morgan and Ward 1986; Pintel et al. 1983). Transcripts encoding the NS proteins are all made from the promoter at 4 map units. Singly-spliced transcripts encode only the multifunctional replication initiator protein, NS1, while further P4-derived transcripts are spliced into an alternate reading frame by removal of the major intron, and encode small nonstructural polypeptides, in order of abundance, NS2P, NS2Y, and NS2L, the extreme carboxy termini of which are different due to the use of alternative 5′ and 3′ splice sites bordering the small intron (Cotmore and Tattersall 1990; Morgan and Ward 1986). One function of NS1 is to up-regulate the P4 promoter itself, and this positive feedback loop appears to be a part of the 'hard-wiring' of infection that insures rapid viral takeover of the cell. A second promoter at 38 map units is *trans*-activated by NS1, as infection progresses (Clemens and Pintel 1988), and drives synthesis of the structural gene transcripts. All P38 transcripts contain a 280 nt 5′ untranslated region located upstream of the minor splice region, and the use of the same alternative 5′ splice sites that are present in the P4 transcripts, regulates synthesis of the capsid proteins. A transcript that employs the downstream 5′ and 3′ splice sites encodes the minor VP1 polypeptide, translation of which initiates at a methionine codon between the two alternate 5′ splice sites. In the more abundant transcripts, which employ the upstream 5′ splice site, this initiation codon is spliced out, and translation of the major coat protein VP2 initiates from a start codon nearly 400 nts further downstream of the splice.

Although parvoviruses may encode several smaller accessory nonstructural proteins, such as the NS2 species

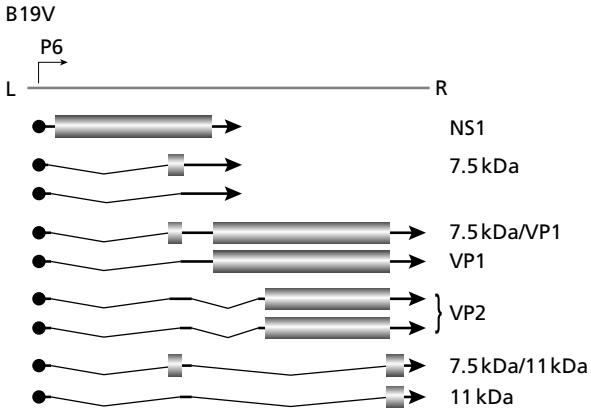

Figure 5 *Gene organization and transcription scheme for members of the* Erythrovirus *genus, as shown for human parvovirus B19 (B19V), annotated as described for Figures 3 and 21.4.*

depicted in the MVM map, only the replication initiator protein, NS1, is absolutely required for replication in all cell types (Bodendorf et al. 1999; Cater and Pintel 1992; Naeger et al. 1990). NS1, or Rep68/78 as it is known in AAV, is an ATP-dependent, site-specific DNA-binding protein with helicase activity, which initiates replication at specific viral origin sequences by introducing a site-specific single-strand nick, thus providing a base-paired 3′ nucleotide to serve as a primer for successive rounds of strand displacement DNA synthesis (Cotmore and Tattersall 1996). The *trans*-esterification reaction that creates this nick leaves NS1/Rep covalently attached to the 5′ nucleotide at the nick site, where it may serve as the 3′ to 5′ replicative helicase. All replicons that use this type of replication mechanism encode their own initiator proteins, and two protein motifs in NS1, representing a putative metal ion coordination site and the active site tyrosine of the nickase, can be traced from the *Parvoviridae* to their prokaryotic 'cousins,' the *Microviridae* (Koonin and Ilyina 1993). MVM NS1 is an 83-kDa nuclear phosphoprotein which self-associates in the presence of ATP to form an oligomeric complex that is capable of binding to a consensus DNA motif found both in the viral origins and at many other locations throughout the genome (Cotmore et al. 1995; Christensen et al. 1995). However, it is only able to nick the DNA in the context of the viral origins, where it encounters the appropriate consensus nick sequence and specific host-derived accessory proteins (Christensen et al. 1997; Cotmore et al. 2000).

Parvoviral replication initiators have evolved into highly pleiotropic proteins, playing multiple roles in the viral life cycle. In addition to their site-specific nicking function, they act as potent transactivators of viral gene transcription, binding to their recognition sequences in viral promoters and activating transcription through acidic carboxy-terminal domains (Legendre and Rommelaere 1994). In MVM, NS1-binding sites are reiterated so frequently that any sequence of 100 base pairs or more contains a site, and some carry multiple tandem and inverted reiterations (Cotmore et al. 1995). This suggests that NS1 likely plays a significant role in viral chromatin structure and progeny strand packaging.

DEPENDOVIRUS GENOMES

Dependoviruses generally have three transcriptional promoters. These are located at 5, 19, and 40 map units along the genome of the type species, AAV2, and transcribe viral mRNAs, as shown in Figure 4, in a temporally regulated fashion throughout infection (Mouw and Pintel 2000; Marcus et al. 1981). P5 transcripts are the first to be expressed, followed by those from P19 and P40, whose protein products are required later in the viral life cycle. P5 transcripts encode the replication initiator proteins Rep78 and Rep68, which appear to serve almost identical functions although they differ slightly in sequence due to splicing of the centrally positioned intron. Spliced messages link the body of *Rep* to a small carboxy terminal segment downstream of the major 3′ splice site, to make the smaller Rep68 protein. In unspliced messages, the sequence encoding the Rep protein body continues on through most of the intron, producing the larger Rep78 protein. Likewise, P19 transcripts encode two Rep forms, Rep52 and Rep48, which differ similarly at their carboxy termini. P40 transcripts are also spliced to alternative 3′ splice sites, and since the downstream acceptor is more efficient than the upstream one, major and minor spliced species are again generated. As an interesting counterpoint to the situation described above for the parvoviruses, in AAV2 the minor VP1 polypeptide initiates from a start codon located between the two 3′ splice sites, rather than between the two 5′ sites, as in MVM. The other AAV2 capsid proteins are then translated from the major, differentially spliced, transcript that lacks the initiation codon used for VP1. The major, and smallest, capsid protein, VP3, initiates from the first AUG codon in this transcript, while the less abundant VP2 species initiates from an upstream in-frame ACG codon. As a result, capsid proteins, VP1, 2, and 3, accumulate in an approximately 1:1:10 ratio, each having identical carboxy-terminal sequences but with VP1 being 137 residues longer than VP2, which is in turn 65 residues longer than VP3. While all AAV2 transcripts coterminate at the right end of the genome, AAV5 has recently been shown to exhibit an additional level of transcriptional control, as shown in the lower panel of Figure 4. Here most of the transcripts encoding nonstructural genes, driven in this case by promoters at 7 and 19 map units, terminate at a central polyadenylation site, located just downstream of the P41 promoter. Cleavage and polyadenylation at this internal site precludes alternative splicing in the Rep transcripts, so that only a single form of the P5 and p19 products are generated (Qiu et al. 2004).

ERYTHROVIRUS GENOMES

The human erythrovirus B19 employs a genetic strategy distinct from those of the other genera, as shown in Figure 5, in that it contains only one promoter, at 6 map units (Ozawa et al. 1987). An unspliced transcript terminating at a central polyadenylation site encodes NS1, while a set of full length transcripts that are spliced in the NS region, encode VP1 and VP2. Two small ORFs can also be accessed by alternatively spliced mRNAs, giving rise to 7.5- and 11-kDa nonstructural proteins. The 11-kDa protein contains three proline-rich regions that conform to consensus SH3 (Src homology 3) ligand sequences (Fan et al. 2001); however, functions for these two protein species remain to be defined. B19 uses two alternative polyadenylation sites, situated similarly to those present in AAV5, as discussed above.

Alternative use of poly(A) sites appears to be controlled by the host cell in a way that suggests that it may act as a major factor in viral tropism (Liu et al. 1992). In a productive infection of erythroid precursors, transcripts terminating at both sites are observed, and give rise to the full array of viral gene products. However, in transfected, nonpermissive cells the central polyadenylation site predominates, and viral gene expression may be largely confined to the synthesis of NS1. This situation is predicted to lead to cytopathogenesis due to the toxic nature of NS1 (Moffatt et al. 1998; Ozawa et al. 1988; Poole et al. 2004), without the production of progeny virus, and may explain in vivo observations of tissue destruction in the absence of B19 growth.

MECHANISMS OF INFECTION

Early events

Steps involved in delivering the viral genome to the host nucleus are illustrated in Figure 6, specifically for members of the genus *Parvovirus* such as MVM. In general, viruses need to achieve a sequence of interactions with the host cell to bring about infection, starting with adsorption to one or more cell surface receptors, internalization (generally in some sort of vesicle), transfer across the cell's delimiting lipid bilayer into the cytoplasm, uncoating leading to exposure of the viral genome, and delivery to the appropriate cellular replication compartment. This pathway is so complex and multifaceted that, while entry is not the only determinant of tropism, it often plays a major role in cell specificity.

Rather than using a single molecule as a cell surface receptor, many viruses employ two more-or-less separate classes of molecules: an 'attachment' receptor, or co-receptor, which effectively accumulates virus in the vicinity of the cell surface; and an infectious-entry receptor that mediates entry into the cytoplasm. While some parvoviruses are known to employ this strategy, the extent to which they rely on multiple surface interactions appears to vary from species to species, and within a species from host cell to host cell, so that few general rules are apparent. MVM binds to sialoglycoproteins present at about 5×10^5 copies per cell on murine fibroblasts, and both binding and infection are neuraminidase-sensitive, indicating a critical role for specific oligosaccharide side chains in these steps. However, at present it is not clear if these comprise one specific cell surface molecule that mediates MVM entry, in addition to others that merely effect attachment, or if all 5×10^5 receptors are equipotent. In contrast, FPV and CPV virions can bind to neuraminidase-sensitive *N*-glycolyl neuramininic acid side chains on some host-cell types, which presumably only function as attachment receptors, since infectious entry is insensitive to neuraminidase and is now known to be mediated by binding to host species-specific protein domains on cell surface transferrin receptor (TfR) molecules (Parker and Parrish 2000). AAVs also use a variety of surface receptors, many of which are widely distributed, but nevertheless fine

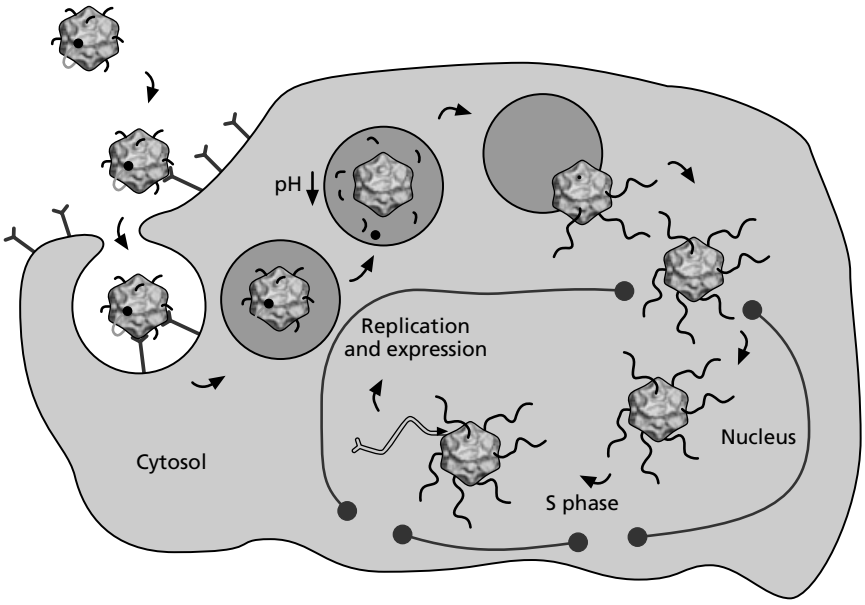

Figure 6 *Entry pathway for a generic parvovirus, as described in the text predominantly for MVM. Short black lines extruding from the virion represent VP2 N-termini, and the single line with a terminal ball represents the tether sequence and its covalently attached NS1 molecule. Longer, gray lines represent the VP1-specific N-terminal extruded upon entry into the cytosol, and the thin double line attached to nuclear virions represents the emerging genome in the process of being converted into double-stranded DNA. See text for additional details.*

details of these interactions have a major impact on effective cell tropism. AAV2 and AAV3 bind the ubiquitous glycosaminoglycan, heparan sulfate, albeit with slightly different specificities (Summerford and Samulski 1998). This may not be all that is required to mediate entry, since AAV2 has also been shown to interact specifically with either α_v, β_5 integrin or basic fibroblast growth factor receptor 1 in ways that ultimately enhance viral gene transduction and hence may function by promoting entry (Summerford et al. 1999; Qing et al. 1999). AAV4 and AAV5 do not bind heparan sulfate, but instead use cell surface carbohydrates carrying the α 2–3 form of neuraminic acid for cell attachment, AAV4 preferentially binding *O*-linked carbohydrates while AAV5 prefers *N*-linked forms (Kaludov et al. 2001). AAV5 then appears to recruit platelet derived growth factor (PDGF) receptors as its primary receptor (Di Pasquale et al. 2003). This is an unexpected finding, since AAVs generally maintain a low profile in their host, and might be expected to enter cells by stealth, whereas PDGF receptors normally respond to ligand-induced cross-linking by autophosphorylating their cytoplasmic tyrosine kinase domains, leading directly to activation of many growth factor response pathways in the host cell. It will be interesting to see whether AAV5 binding does indeed induce receptor-mediated activation, and if so, whether such changes are important in infectious entry by this virus. Finally, the human parvovirus B19 binds to cells of the erythroid lineage via the erythrocyte glycolipid globoside P antigen (Brown et al. 1993). However, a number of cell types that express globoside are not susceptible to infection, suggesting that there could be additional infectious entry receptor(s) for B19 virus.

Following receptor binding, all parvoviruses are rapidly internalized from the cell surface by receptor-mediated endocytosis, predominantly via clathrin-coated pits, and enter an endosome compartment that is sensitive to lysosomotropic agents such as bafilomycin, indicating that low endosomal pH is somehow essential for infection. While members of the genus *Parvovirus* remain sensitive to bafilomycin for up to 6 h after internalization, AAV2 appears to transit into a pH-independent compartment much faster, suggesting that aspects of their penetration mechanisms may be different. Exposure to low pH might be required during entry because it induces essential conformational changes in the virion, because it insures normal endosomal trafficking, or because the viruses specifically need to transit a hydrolase-rich late endosomal/lysosomal compartment to ensure successful entry. Which of these possibilities pertains is currently unclear and is likely to vary between viral species. Indeed, for MVM all three of these processes may be important. Thus, as illustrated in Figure 6, phosphoserinerich amino-terminal peptides from MVM VP2 molecules are displayed at the surface of mature virions, and in some cell types these peptides are known to mediate nuclear export (Maroto et al. 2004), so that removal of all such signals during entry may be essential for the success of subsequent nuclear translocation. This suggests that infectious entry may occur via a late endosomal or lysosomal route, since these are rich in proteases and nucleases, and such exposure would also explain why genomes lose their covalently-linked 5′ NS1 molecules, and the nucleotide 'tether' sequence, prior to arrival in the nucleus (Cotmore and Tattersall 1989).

MVM particles also appear to be stabilized by an acid environment. Amino-terminal sequences of VP1 are known to be essential for entry, but this region is highly protease-sensitive and is sequestered within the virion prior to its entry into the cell. However, the VP1-specific region can become accessible at the particle surface following conformational transitions, inducible in vitro by heating, which are potentiated by the removal of VP2 amino termini, but stabilized by exposure to pH 6.5 or below. Such transitions externalize the VP1 N-terminus and the viral DNA, while leaving the DNA still firmly attached to the otherwise intact particle via its left-end hairpin (Cotmore et al. 1999). Enhanced virion stability during exposure to low pH could thus serve to protect essential hydrolase-sensitive viral structures within an obligate late endosomal/lysosomal entry compartment.

Vesicle trafficking is a complex process that leads to particle delivery to many different cell locations, and trafficking studies typically compound this problem by the use of high multiplicities of input virus needed for signal detection. For example, AAV5 has been reported to enter early endosomelike structures and the cisternae of the trans-Golgi network, but also to accumulate in lysosomes, particularly when applied at high multiplicities (Bantel-Schaal et al. 2002). The high particle-to-infectivity ratios of many viruses also add to this problem, since most of the internalized viruses may enter dead-end circuits that never provide access to the nucleus. This conundrum is well illustrated by recent studies with CPV, which is internalized via an interaction with surface TfRs and presumably remains physically associated with its receptor for at least 4 h, since infectious entry can be blocked throughout that period by intracytoplasmic injection of antibodies directed against the cytoplasmic tails of the receptor (Parker and Parrish 2000). The normal cellular uptake and complex recycling patterns of TfRs have been well studied, and are known to depend upon the presence of a YTRF (Tyr–Thr–Arg–Phe) motif in its cytoplasmic tail. However, when these sequences were deleted or mutated, or polar residues introduced into the TfR transmembrane domain, which vastly increased receptor degradation, virus infection remained efficient (Hueffer et al. 2004). This suggests that infectious entry may involve a minority of TfRs that take, or are directed by the virus to take, an atypical pathway.

Exactly where, or how, these viruses penetrate the endosomal bilayer remains open to conjecture, but CPV infectivity can be blocked by the intracytoplasmic

injection of various antibodies directed against structural determinants in the capsid, indicating that there must be an essential, capsid-associated, cytoplasmic phase (Vihinen-Ranta et al. 2000). VP1 amino-termini carry a PLA2 active site, which is highly conserved among the *Parvoviridae* and appears to be essential for infectivity at some stage following endosomal accumulation, although its role and site-of-action remain to be completely elucidated (Zadori et al. 2001). However, anti-VP1 specific antibodies injected into the cytoplasm have been shown to block CPV infectivity, suggesting that structural transitions leading to exposure of this peptide must accompany entry into the cytoplasmic compartment in vivo, perhaps during transit through the bilayer, as suggested in Figure 6.

The VP1-specific N-terminal region also contains karyopherin-alpha binding sequences, which probably serve to traffic particles to the nuclear pore (Lombardo et al. 2002). Parvoviral particles are very stable and are small enough to be transported through the nuclear pore, so that during infectious entry, viral DNA may remain encapsidated until it is inside the nucleus. Docking of intact particles at the nuclear pore, and/or their translocation into the nucleus has yet to be demonstrated for members of the *Parvovirinae* during natural infection. However, this is likely since recombinant AAV particles have been repeatedly observed in the nucleus, and CPV virions microinjected into the cytoplasm accumulated in the nucleus over a period of 2 h or more where they could be detected with antibodies specific for intact particles (Vihinen-Ranta et al. 2000). Surprisingly, the protracted accumulation of intact recombinant AAV2 virions in the nuclei of liver cells has recently been associated with poor expression of virally-coded transgenes, whereas exactly similar genomes pseudotyped into AAV6 or AAV8 coats were uncoated more rapidly and transcribed more efficiently. This has led to the hypothesis that, for optimal expression, AAV virions must be trafficked to a specific site in the nucleus, where uncoating is efficiently induced by interaction with unidentified nuclear factors, and that AAV2 particles fail to achieve this intranuclear translocation (Thomas et al. 2004).

Parvoviruses are unable to induce resting cells to enter S phase, and it is not until infected cells enter S phase of their own volition that viral transcription normally initiates. Since the viral promoters are packaged as single-stranded DNA, acquisition of a complementary strand necessarily precedes viral gene expression, and its synthesis likely represents the first S phase dependent step in the viral life cycle. Initial transcription of MVM also depends upon the availability of the host transcription factor E2F to activate its P4 promoter, so that viral transcription is optimized for expression during S phase (Deleu et al. 1999). As early MVM gene products accumulate, host-cell DNA synthesis is terminated and progression through the cell cycle is suspended, but the molecular mechanisms underlying these interactions have yet to be elucidated. In contrast to the helper independent parvoviruses, productive AAV infection relies upon the ability of its helper virus to drive resting cells into S phase, and even in the absence of cellular replication some viral transcription may occur at high input multiplicities, from duplex episomes generated by the annealing of opposite sense input strands (Nakai et al. 2000), as will be discussed later.

DNA replication

Parvoviral DNA is replicated through a series of duplex, concatemeric intermediates by a strand displacement mechanism called rolling hairpin replication (RHR), depicted in Figure 7 (Cotmore and Tattersall 1996; Tattersall and Ward 1976). The replication fork is aphidicolin-sensitive, requires PCNA, is unidirectional and results in the synthesis of a single, continuous DNA strand, indicating that synthesis is probably mediated predominantly by DNA polymerase δ and its accessory proteins (Ni et al. 1998; Christensen and Tattersall 2002). Short imperfect palindromic sequences at each end of the genome repeatedly fold and unfold during this process, first creating duplex hairpin telomeres in which the 3′ nt of each strand is paired to an internal base to create a DNA primer, and then unfolding to allow the hairpin to be copied. Together with a few flanking nucleotides, these palindromes contain all of the *cis*-acting information needed for both viral replication and packaging. During RHR they effectively serve as 'toggle-switches,' reversing the direction of synthesis at each end of the linear genome, thus adapting the more ancient rolling-circle replication strategy (Ilyina and Koonin 1992) for the amplification of a linear chromosome.

Since MVM packages negative-sense strands predominantly, and hence the 3′ end of the DNA is always at left end of the incoming genome, it is easier to describe the rolling hairpin process for this virus, but exactly parallel steps ensue for incoming positive strands of all genera, except that replication would initiate at the right-end of such genomes. Thus, for MVM in step (i) of Figure 7, the base-paired 3′ nucleotide of the left-end hairpin is used by a host polymerase to prime conversion of virion DNA to the first duplex intermediate. This generates a monomer length duplex molecule in which the two strands are covalently continuous at the viral left-end telomere. Synthesis of this intermediate precedes viral gene expression. The cellular replication fork assembled on such viral templates appears to be unable to displace and copy the right-end hairpin sequence, so the 3′ end of the new DNA strand is ligated to the 5′ end of the hairpin by a host ligase, creating a covalently continuous duplex molecule (Cotmore and Tattersall 1996) (step ii). Replication

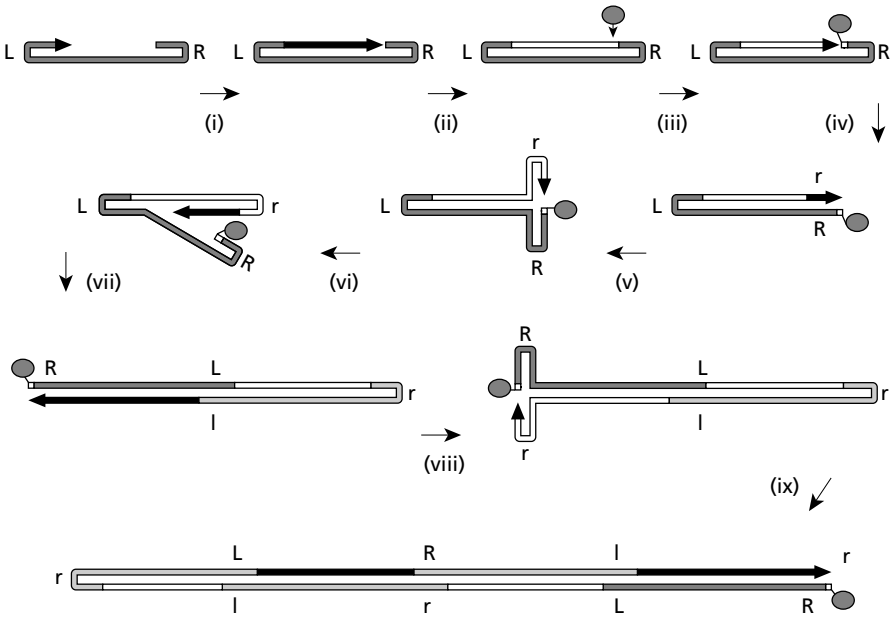

Figure 7 *Parvoviral 'rolling hairpin' DNA replication scheme. The viral genome is represented by continuous line, shaded dark gray for the original genome, light gray for progeny genomes, and black for newly synthesized DNA, the 3′ end of which is indicated by the arrowhead. The gray sphere represents an NS1 molecule. The letters L and R represent left-end and right-end palindromic sequences, respectively. Upper and lower case represent 'flip' and 'flop' versions of these sequences, respectively, which are inverted complements of one another. See text for further explanation.*

beyond this point requires expression of the viral initiator protein, NS1 in MVM or Rep68/78 in AAV, which nicks the ligated strand, as illustrated in Figure 7, step (iii), in a reaction that is assisted by a host DNA-bending protein from the HMG1 family. This requirement for HMG1 appears to vary somewhat between genera, being essential for the MVM right-end telomere, but merely enhancing initiation at the AAV2 hairpins (Costello et al. 1997; Cotmore and Tattersall 1998). Nicking is achieved by a transesterification reaction, which liberates a base-paired 3′ nt that supports the assembly of a new replication fork, while leaving NS1 covalently attached to the 5′ end of the DNA at the nick, where it is believed to function as the 3′ to 5′ replicative helicase of the subsequent replication fork (Christensen and Tattersall 2002; Smith and Kotin 1998; Wu et al. 1999; Zhou et al. 1999). NS1 also recruits the cellular RPA (replication protein A) complex, which binds and stabilizes single-stranded DNA, while AAV appears to favor adenovirus single-stranded binding protein, although in either case the availability of such factors appears rate-limiting for the progress of this strand displacement mechanism (Ward et al. 1998; Christensen and Tattersall 2002).

A complex sequence of melting and reannealing reactions then ensues, step (iv–v) Figure 7, in which the replication fork, assisted by the initiator protein, first unfolds and copies the hairpin, in a process called 'hairpin transfer,' thus replacing the original sequence of the terminus with its inverted complement (step iv). Since the terminal sequences are imperfect palindromes, and this inversion occurs with every round of replication, progeny genomes comprise equal numbers of each terminal orientation, dubbed 'flip' and 'flop.' In MVM the entire sequence of reactions from the introduction of the NS1-mediated nick to the generation of a duplex extended-form telomere is referred to as 'hairpin resolution,' while in AAV the equivalent sequence of events is called 'terminal resolution' (Snyder et al. 1990; Cotmore and Tattersall 1996). A general rule seems to be that viruses with identical termini, like the AAVs and B19, replicate both termini by hairpin resolution, and thus have flip and flop forms of each telomere, while viruses with disparate termini, like MVM, replicate the right-end by hairpin resolution and the left by an asymmetric mechanism, called junction resolution, which conserves a single sequence orientation and uses different structural arrangements and cofactors to activate the NS1 nickase, as discussed below.

The extended-form duplex termini generated in step (iv), Figure 7, are then melted out and the strands reformed into hairpinned 'rabbit ear' structures, in a process facilitated by the direct binding of NS1 to symmetrical copies of its duplex recognition sequence surrounding the axis of the extended palindrome (Willwand et al. 2002; Ward and Berns 1995) (step v). This allows the 3′ nucleotide of the newly synthesized DNA strand to pair with an internal base, thus priming synthesis of additional linear sequences (step vi). The result of rolling hairpin synthesis is the accumulation of

palindromic duplex dimeric (step vii) and tetrameric (step ix) concatemers, in which alternating unit length genomes are fused in left-end–left-end and right-end–right-end orientations. Although such concatemers are generated during AAV replication, they tend to be heterogeneous because both ends of the genome can be excised by equivalent reactions, whereas in MMV, left-end–left-end dimer duplexes accumulate, awaiting resolution by the more complex, and apparently slower, junction resolution process.

During junction resolution, left-end sequences are replicated and separated asymmetrically, so that new termini are created in a single sequence orientation, designated 'flip.' This effectively allows the two arms of the hairpin to be dedicated to different roles in the viral life cycle, the outboard arm supporting resolution, while the inboard arm potentially provides upstream elements for the nearby transcriptional P4 promoter. The 121 base left-end telomere of MVM has an important unpaired 'bubble' element in the hairpin stem, where a trinucleotide on the inboard arm opposes a mismatched dinucleotide. During rolling hairpin synthesis this hairpin is unfolded and copied to form the left-end–left-end junction, which links monomer genomes in the dimer intermediate (Figure 7, step vii), and within which these asymmetric bubble nucleotides segregate to opposite sides of the junction. It is this duplex junction structure, rather than a single hairpinned terminus, which contains the replication origin required for copying and separating MVM left-end sequences. The junction contains one candidate nick site for NS1 on each arm of the palindrome, located on opposite strands, but only the origin on the arm carrying the 'bubble' dinucleotide has the precise spatial organization required for nicking to occur. This is because, at the left-end origin, activation requires a cellular protein, called parvoviral initiation factor (PIF), to bind the viral DNA in exact juxtaposition to NS1 (Christensen et al. 1999). This interaction occurs only across the dinucleotide, and not the trinucleotide, bubble spacer element. PIF effectively stabilizes the binding of NS1 to its recognition element in the active origin, allowing it to use its 3′ to 5′ helicase activity to melt the duplex DNA at the adjacent nick site (Christensen et al. 2001). This is an essential prerequisite for nicking because, like other rolling-circle initiator proteins, NS1 is only able to nick its cognate site if this is presented as single-stranded DNA. The formation of individual nicking complexes and the biochemistry of these reactions have been studied extensively, but are largely outside the scope of this article, and the interested reader is referred to the more detailed discussions in the references cited above.

Following introduction of a single nick in the active arm of the junction, the 3′ to 5′ helicase activity of NS1 destabilizes the palindrome, frequently promoting its rearrangement into a cruciform intermediate that is essential for junction resolution. Replication forks that assemble after the junction reconfigures into this cruciform synthesize DNA in the flip orientation, creating a heterocruciform structure, which then undergoes a form of hairpin transfer. Ultimate resolution of the resulting, partially single-stranded, product requires the introduction of an NS1-mediated nick in the 'inactive' arm of the junction introduced as this is transiently presented in single-stranded form to the nickase (Cotmore and Tattersall 2003). Operationally, whether or not this final single-strand nick occurs is thought to depend upon the efficiency of hairpin resolution at the right end of the genome, since forks returning from the right end could recreate the partially resolved duplex junction before the single strand nick occurs. Thus the speed of initiation at the right-end of the genome influences the products generated at the left-end of the genome, a theme which becomes important when considering which strands are ultimately packaged, as discussed below. Although junction resolution appears complex, it uses a series of reactions that are characteristic of parvoviral replicons and their replicator proteins, and may represent a way of resolving junctions so that each arm could be dedicated to a different activity. That this might indeed be the case is suggested by studies with MVM genomes that have been mutated to present an active origin on both arms of the left telomere. Such mutations are invariably lethal, but allow the selection of viable variants in which the origin associated with the inboard arm has been inactivated by a variety of secondary mutations, suggesting that restricting cleavage at the inboard site is essential (Burnett and Tattersall 2003).

Capsid assembly and packaging

Late in infection, viral capsid gene expression predominates because NS1/Rep is able to strongly *trans*-activate the P38 promoter (Rhode 1985; Labow et al. 1986). As illustrated for MVM in Figure 8, VP1 and VP2 are synthesized in approximately the ratio required for capsid assembly. Partially assembled capsid subunits, probably in the form of trimers, exhibit a structure-dependent nuclear localization signal on a VP-common β-strand that will eventually form part of the internal surface of the capsid. This directs translocation of the intermediates into the nucleus, where they are assembled into empty capsids, which are believed to be the precursors of full virions. For AAV2 assembly appears to occur within the nucleoli, which also become highly disorganized in many other parvovirus infections (Singer and Rhode 1978; Wistuba et al. 1997). In MVM infection of murine cells some aspect of the continued synthesis and assembly of the capsid precursors requires the small nonstructural polypeptide NS2 (Cotmore et al.

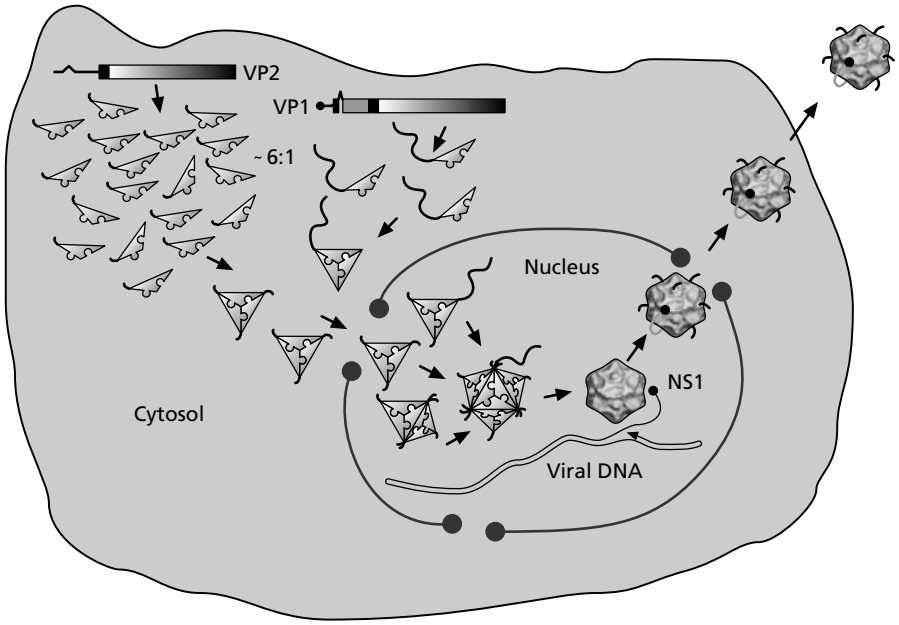

Figure 8 *Assembly and packaging pathway for a generic parvovirus, as described in the text predominantly for MVM. Lines and blocks at top left indicate the P38-driven transcripts and their encoded protein sequences. The core VP sequence that is the building block for the particle is shown as a gray gradient-filled box in the coding diagram, and a triangular icon as its translated form. Shading of VP components and identity of other symbols are described in the legend to Figure 6. See text for additional details.*

1997). Significantly, when empty capsids are assembled, the VP1 and VP2 N-termini are internalized, so that both the VP1-specific and VP-common nuclear localization signals are hidden within the particle, while the VP2 N-termini, which contain a nuclear export signal discussed later, are also effectively concealed from the export machinery. Thus empty capsids appear to be entirely neutral with regard to intercompartmental trafficking.

As assembled capsids accumulate, progeny single-stranded DNA synthesis begins to predominate over duplex DNA amplification. How this switch is controlled is unknown, but progeny synthesis is entirely dependent upon the availability of preformed capsids, and most of the single-stranded monomeric DNA in the cell appears to be encapsidated. Exactly how DNA strands are selected for packaging remains uncertain, but the minimal requirement appears to be the presence of an active nick site (Nony et al. 2003; Musatov et al. 2002; Huser et al. 2003). Since the viral initiator proteins, NS1 and Rep68/78, become covalently attached to the DNA at such sites, and because these proteins bind efficiently to intact capsids (Dubielzig et al. 1999), they may well mediate the initial interactions. Selection of positive or negative sense DNA is not directed by strand-specific packaging signals, but rather reflects the relative efficiencies of the viral replication origins associated with the two genomic termini (Chen et al. 1989; Cotmore and Tattersall 2005). However, since packaging requires ongoing viral DNA synthesis, it is not simply a process of melting out and sequestering preformed DNA strands (Myers and Carter 1980; Zhou and Muzyczka 1998). Strands are packaged vectorially, in a 3′ to 5′ direction, driven in AAV2 by the helicase activity of the small Rep proteins, Rep40 and Rep52 (King et al. 2001). As DNA is translocated into the MVM particle, approximately 25 amino acids of a VP2 N-terminus becomes externalized through the pore in each of the 12 cylindrical turrets protruding from the capsid surface at the fivefold symmetry axes (Agbandje-McKenna et al. 1998; Xie et al. 2002; Cotmore et al. 1999). This region of the VP2 polypeptide carries a series of phosphorylated serine residues and can be shown to function as a nuclear export signal, causing full virions to be translocated into the cytoplasm, and hence out of the cell via an as yet unknown route, prior to lysis (Maroto et al. 2000; Maroto et al. 2004). Thus, the act of packaging converts a trafficking-neutral capsid to a nuclear export competent virion.

NS2 is involved in this early exit pathway, even in cells where it is not required for capsid assembly, and part of this function appears to be mediated via a binding motif for the nuclear export protein, Crm1, located in its central exon (Ohshima et al. 1999; Miller and Pintel 2002; Bodendorf et al. 1999). During normal infection, NS2 is predominantly cytoplasmic, but mutations in the Crm1 binding site reveal it to be a constitutively nuclear protein, which is normally transported out of the nucleus via a Crm1-dependent pathway. Early virion release is impaired in such mutants, but it is not yet clear whether Crm1-complexed NS2 simply acts by inducing essential changes in the cellular environment,

or whether it acts through a direct interaction with the particle. Ultimately infections are generally lytic, and cells remain actively synthesizing viral DNA until necrotic or apoptotic lysis occurs at about 16–20 h after entry into S phase (Ran et al. 1999; Rayet et al. 1998), which results in significant release of residual progeny virions.

HOST RANGE

Tissue and host species specificity

Lytic growth is modulated by developmentally regulated factors operating in the host at the cellular level. Significant differences in target tissue specificity clearly exist between different parvovirus species. These can often be explained by the use of a different cell surface receptor repertoire by each virus serotype, as discussed elsewhere in this chapter, although postentry blocks to viral growth have also been identified in some virus–host combinations. However, differences in pathogenic potential exist not only between virus serotypes, but between virus strains of the same serotype, as seen within the MVM, PPV, FPV, and AMDV species. The prototype strain of MVM, MVMp, productively infects murine fibroblasts, but cannot establish infection efficiently in T lymphocytes. The isolation of a second strain of minute virus of mice, MVMi, as an immunosuppressive agent from a murine lymphoma (Bonnard et al. 1976), indicated that a mutable genetic component of the virus played a role in determining the type of differentiated cell the virus can lytically infect. For MVM, this discrimination is mediated by a region of the viral capsid called the allotropic determinant, which acts in *cis* with the genome it encapsidates (Gardiner and Tattersall 1988a,b). The determinant involves a small group of amino acids that map near the surface of the virion, grouped along the edge of the spike at the threefold symmetry axis and down into the depression at the two-fold axis (Agbandje-McKenna et al. 1998). Here a coordinated change in just two amino acid residues in the capsid of the lymphotropic murine virus MVMi allows it to extend, or even switch, its host range, gaining the ability to replicate productively in murine fibroblasts (Ball-Goodrich and Tattersall 1992).

Genetically and pathogenically distinct strains of PPV also exhibit allotropic specificity determined in a similar way, which controls their ability to replicate in particular porcine cell lines in vitro (Bergeron et al. 1996), and AMDV replication has been similarly linked to a cluster of capsid residues (Fox et al. 1999). Studies on MVM, PPV, and AMDV strains have shown that infection of the 'wrong' host cell is profoundly restricted at an, as yet, unidentified step, which occurs after virus internalization from the cell surface, but before the onset of transcription and DNA amplification. Significantly, while each MVM strain is reciprocally restricted in each other's host cell, both strains replicate efficiently in somatic cell hybrids between the two host-cell types, implying that restricted infections fail to establish because of the absence of a differentiated host factor in the restrictive host that is usually exploited by the restricted strain in its permissive cell type. However, the molecular identities of the host factors that mediate these strain-specific tropisms remain elusive, and may well vary between virus–host combinations.

While control of species host range among viruses from the FPV/CPV group is determined by a similar cluster of surface amino acid changes in the capsid (Chang et al. 1992; Parrish 1991; Truyen and Parrish 1992), these changes are now known to act via species-specific interactions with the viral cell surface receptor, recently shown to be the TfR (transferrin receptor). Thus, while all of the viruses can bind to feline and human TfR, and use these receptors to enter and infect cells, canine cell infection is a specific property of CPV and depends on the ability of this virus to bind the canine TfR (Govindasamy et al. 2003; Parker et al. 2001; Hueffer et al. 2003). The specific contact established between CPV or FPV capsids and the TfR also appears to be important, since modifications introduced into either the virus or receptor can allow cell surface binding to occur without leading to infection (Hueffer et al. 2004). For these viruses, the critical step likely involves receptor-mediated internalization of the virus in a way which selectively leads to its successful translocation across the endosomal bilayer, but how or where this operates remains uncertain.

The situation for MVM appears to be substantially different. Both fibrotropic and lymphotropic strains of MVM bind to sialoglycoproteins present at about 5×10^5 copies per cell on murine fibroblasts, and compete for binding to these receptors (Spalholz and Tattersall 1983). While all of these receptors could be equipotent, it is still possible that different minor classes of specific cell surface molecules mediate cytoplasmic delivery of MVMi and MVMp, while the more abundant species merely effect surface attachment. Thus a cytoplasmic delivery mechanism, like that conjectured for CPV, remains a possibility for MVM whereby both virus strains are internalized into endosomes on a variety of receptors, but can only penetrate the bilayer successfully from a particular receptor species. Precedent for this type of restriction has been documented for the 'small plaque' mutants of polyomavirus (Bauer et al. 1999), which vary from wildtype in binding avidly to entry-incompetent receptors. However, restriction to the extent seen for MVM, which would require most of the virus to be bound on incompetent receptors, has yet to be described. Alternatively, capsid-mediated MVM host range restriction could operate at a later stage in the life cycle, and involve a selective interaction between the virion and cell type-specific host molecules that mediate

nuclear entry, viral uncoating, or the assembly of the initial viral transcription templates. In this respect, it is interesting to note that recent studies suggest that the uncoating of recombinant AAV particles shows virus species-specificity in rat liver cells, with AAV6 and AAV8 virions being uncoated much more efficiently than their AAV2 counterparts, possibly because the latter are not delivered to nuclear loci containing host factors that mediate this transition (Thomas et al. 2004).

Tissue specificity can also be mediated in MVM after the onset of infection, by sequences that map to a region in the nonstructural gene containing the splice control regions for the major intron (Rubio et al. 2001; Gardiner and Tattersall 1988b; Colomar et al. 1998). Splicing efficiency at this intron, which can be modulated by single nucleotide mutations in the putative splice branch point region, determines the relative levels of NS1 and NS2 transcripts generated during infection, with growth in fibroblasts apparently requiring the more efficient NS2 splice configuration, while the opposite is true for growth in lymphocytes. However, the level at which this tropism operates remains to be determined. The absolute ability to express NS2 has also been identified as a host range determinant, since MVMp NS2-null mutants, which cannot express any of this protein, are completely defective for growth in murine fibroblasts, although they are able to replicate in a number of cell types, notably transformed human fibroblasts (Naeger et al. 1990). At present it is not clear whether this phenomenon represents a true host species restriction or if transformation of a normally nonpermissive host cell can sometimes complement for the lack of NS2, thus rendering the cell permissive for NS2-null virus replication.

Oncotropism

The affinity of parvoviruses for dividing cells is also reflected in their ability to interfere with, and suppress, another type of rapid cellular proliferation in their hosts, namely, neoplastic disease. Infection with autonomous parvoviruses has been shown to suppress tumor formation by a large number of viruses and carcinogens. For example, KRV suppresses leukemia induction in rats by Moloney murine leukemia virus (MoMLV) (Bergs 1969), and H1 infection of hamsters suppresses tumor formation by either adenovirus or dimethylbenzanthracene (Toolan and Ledinko 1968; Toolan et al. 1982). Similarly, AAV2 has been shown to inhibit the oncogenicity of tumor viruses and transformed cells (de la Maza and Carter 1981; Katz and Carter 1986), although in this case the effects may predominantly reflect the complex interactions between AAVs and their helper viruses.

Despite their apparent lack of natural infectivity for humans, rodent parvoviruses can grow in many human cell lines in vitro, and this is especially true if the cells are transformed by agents such as gamma-rays, nitroquinolines, or SV40 (Cornelis et al. 1988). Extensive studies over the past two decades, focusing on MVM and H1, have defined in vitro analogues of this oncotropism, and have established that it is a cell-intrinsic, rather than an immune-mediated phenomenon. Sensitization to parvovirus-mediated cell killing has been demonstrated following transformation of rodent and human fibroblasts, human keratinocytes and human mammary epithelium. Transforming agents used have varied from activated oncogenes such as h-*ras* and v-*src*, to c-*myc* and papovaviral T antigens (Rommelaere and Cornelis 1991). The biochemical basis for such sensitization is complex, and can take several forms. In some cells it manifests as a dramatic, transformation-associated increase in viral DNA amplification, while in others it can present as transcriptional up-regulation of the P4 promoter, combined with a significant lowering of the threshold concentration of viral NS proteins above which cell survival is drastically impaired (Caillet-Fauquet et al. 1990). In *ras*-transformed cells, a significant proportion of this P4 promoter up-regulation is known to be controlled by two separate transcription factor-binding sites upstream of its TATA box, one specific for members of the CREB/ATF family, while the other binds factors belonging to the Ets family (Perros et al. 1995; Perros et al. 1999; Fuks et al. 1996). Transformation-induced modulation of normal cell cycle control thus appears to promote viral replication, and pathogenicity, by impinging upon several different processes in the viral life cycle. Since it clearly does not relate entirely to their requirement for rapidly dividing cells, it is not clear why the parvoviruses should exhibit these oncotropic properties, particularly those controlled by the P4 promoter. It may be that this property has been fortuitously selected for by its natural growth in developing, particularly neonatal, hosts, where aspects of the intracellular milieu of its target cell populations may be mimicked by some of the events that contribute to transformation in the adult cell types. In support of this possibility, is the recent observation that *LacZ* expression is controlled in a cell-type-specific and differentiation-dependent pattern during embryogenesis in mice transgenic for an MVM P4-driven β-galactosidase reporter gene, indicating that P4 is markedly responsive to developmental signals (Davis et al. 2003).

Persistence: latency and cryptic infection

The first direct evidence for parvoviral latency came from the observation that adenovirus infection of some primary human embryonic kidney cultures would yield infectious AAV particles that were not detectable in the original adenovirus stock. Subsequently, it was shown that propagation of human Detroit 6 cells,

infected with AAV in the absence of adenovirus, led to the gradual disappearance of demonstrable AAV, which could then be recovered by subsequent adenovirus infection. This led to the hypothesis that AAV could persist in cells in a latent, inheritable form (Berns et al. 1975). The advent of Southern blotting allowed the identification of AAV genomes in such cells, integrated into chromosomal DNA as tandem repeats (Cheung et al. 1980). Subsequent studies have shown that the integration of AAV genes is dependent upon the presence of the *Rep* genes. While the *Rep* gene products up-regulate their own synthesis during coinfection of AAV2 with a helper adenovirus, when AAV2 infects on its own this feed-back effect of Rep is reversed and Rep production is shut down. However, between 1 000 and 4 000 Rep molecules are produced per cell, and this is enough to catalyze the integration of the viral genome into a specific site at chromosome 19q13.3-qter in the human genome (Kotin et al. 1990). Specific integration at this chromosomal locus requires the interaction of Rep with a target DNA sequence that has key features in common with the origin of AAV DNA replication embedded in each viral terminal repeat (Kotin et al. 1992). When the chromosome 19 sequence, known as AAVS1, is placed in a plasmid, it can serve as a substrate for Rep-dependent DNA replication in an in vitro system (Urcelay et al. 1995), and when present as a 'knock-in' transgene in the mouse X-chromosome, it will direct site-specific integration of AAV2 in murine cells (Young et al. 2000). Cloned into an Epstein–Barr virus (EBV) episome and transfected into human cells, the AAVS1 sequence supports site-specific AAV2 integration in vivo, which provides a system where integration can be genetically manipulated (Giraud et al. 1994). Studies using this system have confirmed that AAVS1 must be able to function as an AAV replication origin in order to serve as an integration target site (Linden et al. 1996). In addition, it appears to be important that chromatin associated with the AAVS1 locus is in an open configuration, as shown by the presence of a nearby active gene, encoding slow skeletal troponin T (Dutheil et al. 2000), a DNase I hypersensitive site (Lamartina et al. 2000), and an upstream insulator element that blocks the spread of heterochromatin over the locus (Ogata et al. 2003). In the absence of the Rep 68/78 protein, AAV2 still integrates into the host genome, but at multiple, and apparently random, sites, although there still seems to be a bias towards actively transcribed genes (Nakai et al. 2003). It seems likely that these integration events involve pre-existing double-strand breaks in the host chromosome (Song et al. 2001).

Early studies showed that the autonomously replicating parvoviruses do not integrate into host DNA during a normal infection cycle (Richards and Armentrout 1979). While no stable cell lines carrying integrated genomes resulting from helper-independent parvoviral infections have been reported, MVM has been shown to integrate site-specifically into an episomal EBV-based shuttle vector in a permissive cell, provided the left-end viral replication origin, containing a nick site for NS1, is present (Corsini et al. 1997). Interestingly, no integration was detected into episomes harboring a functional right-end origin. Isolation of such integrants was achieved by recovering the targeted shuttle vector by transfection of DNA derived from the dying cell culture into a bacterial host. This suggests that the reason stable integrants cannot normally be obtained from parvovirus-infected cell cultures is that such interactions, if or when they occur, do not confer protection against subsequent lytic infection, and thus the integrants cannot survive as clonal lines. Significantly, it has also been shown recently that MVM genomes that lack active *NS1* genes also integrate efficiently in a nonsite-specific fashion, at an efficiency that is comparable to that of Rep-negative AAV (Hendrie et al. 2003). Thus, random integration is possibly a feature common to all parvoviral genomes in situations where they are unable to express their NS genes and kill their host cell.

Although the helper-independent parvoviruses are inherently lytic, they are also exquisitely dependent on the host cell-cycle program, because while they are unable to force cells to proliferate, they require their host to enter S phase to support replication and transcription. This leads to another potential form of persistence, in noncycling cells, which has been dubbed cryptic infection, to distinguish it from the latent infections described previously for AAV. In cryptic infection, the viral life cycle does not proceed further than nuclear sequestration of the incoming virion, and is thus completely silent with respect to viral gene expression. Thus, in resting peripheral blood lymphocyte cultures, infectious virus has been observed to remain sequestered and initiate replication only after the addition of phytomitogens (Paul et al. 1979). This type of interaction is inherently unstable, and cannot persist by vertical transmission, in vitro or in vivo, because when a cryptically infected host cell enters S phase, in response to an exogenous signal, its resident virus will initiate replication, express its genes, and the cell would subsequently die (Tattersall and Gardiner 1990).

The application of highly sensitive PCR techniques to patient-derived material has recently led to the realization that B19 genomes are retained at low levels in a variety of tissues in infected individuals over the course of many years (Soderlund-Venermo et al. 2002). Possibly such viruses emerge at intervals, and boost host immunity, explaining why anti-B19 antibody titers are routinely maintained for life. At present, it has not been established whether the B19 genomes found in each of these situations persist as cryptic or latent state, as intact virions, integrated proviruses or episomal complexes.

PATHOGENESIS OF PARVOVIRAL INFECTION

INFECTIONS WITH MEMBERS OF THE *PARVOVIRUS*, *AMDOVIRUS*, AND *BOCAVIRUS* GENERA

Epidemiology

Parvoviruses are generally widely disseminated in their natural hosts. In part this is due to their high level viremias and efficient transmission via bodily secretions and excretions, and in part to the fact that infectious particles are exceptionally rugged, so that they survive outside their host for extended periods. Thus when CPV, a new virus in the feline panleukopenia serotype, emerged as a pathogen of dogs in 1978, it spread through most of the world within a few months, probably because it remained fully viable in fecal material transported on the shoes of airline passengers. Exactly how long shed virions retain viability in nature is undocumented, but they are resistant to most normal ambient temperature ranges, for instance, the half-life for MVM infectivity is in excess of 9 months at refrigerator temperatures. Statistics for virus distribution in wild animal populations are not readily available, but many, such as MPV and H1, are known to be widespread. Infection is generally acute and self-limiting, with transient viremias that last for 7–10 days while the host seroconverts, but some viruses, such as KRV, persist despite high neutralizing antibody titers, so that infected individuals may routinely shed virus for many months (Robey et al. 1968). With the advent of sensitive PCR technology it has become apparent that even following acute, apparently self-limiting infections in immune-competent hosts, low levels of viral DNA are routinely retained in some tissues for many years, although whether this DNA is episomal, cryptic, or integrated is uncertain.

Wild populations of the natural host generally have a high incidence of neutralizing antibody, so that most mothers transmit immunity to their offspring. Thus, infection of neonatal or nursing animals as maternal antibody wanes leads to an active, long-lasting immune response, rather than overt disease. As a consequence, clinically manifest infection is a rare event under endemic conditions, and is generally observed only in immunocompromised individuals. However, in veterinary medicine, vaccination of the entire population is a routine procedure because in domestic animal populations, epizootic and even panzootic, crises may develop if a virus is introduced into an immunologically naive host population.

Pathogenesis

Since their discovery at the end of the 1950s, viruses from the genus *Parvovirus* have been recognized as potential pathogens, although many of them have coevolved with their host to such an extent that infection generally remains subclinical. The spectrum of parvovirus disease thus ranges from acute lethal infections, through slowly progressing, sometimes chronic, illness, to transient subclinical malaise. Somewhat surprisingly, there are no known members of the genus *Parvovirus* that productively infect humans, although several can enter and initiate infection in normal human tissues in culture, or replicate productively in transformed human cell lines.

The types of pathology associated with viral infection can be readily understood by considering a few basic biological principles that control the viral life cycle. Firstly, parvoviruses all exhibit tissue specificity, which limits their lytic potential to cells of particular differentiated types, although this specificity may vary widely between virus species. As discussed previously, tissue specificity is frequently mediated by the presence or absence of appropriate cell surface receptors and coreceptors. However, it also commonly occurs at later stages in the infectious cycle, since the limited genetic complexity of these viruses means that they are peculiarly dependent upon exploiting the synthetic pathways of their chosen host. Disease potential is also controlled by their lack of growth control genes, so that, unlike most DNA viruses, they have no mechanism for forcing noncycling host cells to enter S phase, even though they depend absolutely upon cell functions expressed transiently during this phase of the cell cycle. Thus productive viral replication, and even viral gene expression, is restricted to proliferating cell populations. As lytic parasites of dividing cell populations, their ability to cross the placenta means that they can be potent teratogenic agents, causing fetal and neonatal abnormalities by destroying specific cell populations that are rapidly proliferating during the course of normal development. Indeed, the first autonomous parvoviruses were discovered because of their teratogenic potential in laboratory rodents. These same tissues are often quiescent, and therefore resistant, in the adult.

The age of the infected host thus profoundly influences susceptibility, since it determines the availability of mitotically active cells of the correct differentiated type. Age also influences the viruses' pathologies by determining the degree to which tissue regeneration can take place, so that viruses that replicate in tissues or organs capable of efficient regeneration, such as the liver in a young animal, lead to acute but self-limiting disease with no permanent damage, while the destruction of tissues with limited regenerative potential, such as the developing cerebellum, leaves permanent defects (reviewed in more detail in Siegl 1984, 1988).

INFECTION OF FETAL AND NEONATAL HOSTS

Fetuses and neonates are particularly susceptible to disease. If infection occurs early in pregnancy, the effects on the fetus tend to be generalized, and often

fatal, thus viruses infecting pigs, cows, rodents, and mink are commonly associated with fetal wastage. By the late pregnancy, and in neonatal animals, infection tends to be less devastating, coinciding with the increasing ability of the developing host to mount an effective immune response. As the patterns of cell division and differentiation change during development, infection also becomes more organ-specific and leads to distinct syndromes. Thus, infection with FPV or some of the rodent parvoviruses late in gestation specifically induces cerebellar ataxia by lytically targeting, or inducing apoptosis in, cells in the outer germinal layer of the differentiating cerebellum. Newborn mink infected with AMDV develop a severe, potentially fatal, respiratory distress syndrome, resulting from destruction of the type 2 alveolar pneumocytes that are proliferating during this period, while puppies infected with CPV in a time window between 8 days before and 5 days after birth show evidence of viral replication in the developing myofibers, leading to a fatal interstitial myocarditis (reviewed in Bloom and Young 2001). Most dramatically, lytic replication of some rodent parvoviruses in osteogenic tissues that are active during the perinatal period can lead to severe craniofacial and dental deformities, the so-called osteolytic syndrome, which results in offspring with small flat faces, microcephalic heads, protruding eyes and tongue, missing or abnormal teeth, and fragile bones (Siegl 1984, 1988).

INFECTIONS OF MATURE HOSTS

In older animals, more tissues are mitotically quiescent, so that acute disease is generally limited. However, some adult tissues, such as gut epithelium and the lymphopoietic system do retain large numbers of cycling cells. The small subset of autonomous parvoviruses that are capable of effectively targeting these cells, most notably viruses from the FPV/MEV/CPV complex, typically cause fatal disease in adult animals involving extensive destruction of gut epithelium and reticuloendothelial cells, while less extreme forms of leukopenia are also associated with PPV, BPV, and some rodent virus infections. Hepatitis is another common outcome of parvoviral disease in the post neonate, associated with protracted mitotic activity in the maturing liver, or damage-induced cell proliferation in adult tissue. While overt liver disease is a major symptom of GPV infections of goslings, hepatic damage associated with most viruses is rarely lasting because hepatocytes regenerate efficiently following immune clearance of the infecting virus. Patterns of acute disease in the adult thus directly reflect the replicating target tissues available at that time, and are often different from the patterns established by the same virus in the fetus or neonate (Siegl 1984, 1988).

A second, chronic, type of disease may also result from viral infection in the mature animal, associated with the immune response of the host. Thus, AMDV gives rise to a persistent infection in adult mink involving the antigen-presenting cells of the immune system, which ultimately results in immune-complex mediated glomerular nephritis. As a result, while vaccination is generally protective against most acute parvoviral disease, it can be contraindicated for viruses such as AMDV where it actually serves to intensify the pathology (Bloom and Young 2001).

INFECTIONS OF IMMUNOCOMPROMISED HOSTS

Infection of normal and mutant mice with MVM has shown that otherwise lethal pathogenic interactions between the virus and its host are effectively controlled by the host's immune system. Thus, MVMi is essentially apathogenic in adult animals (Segovia et al. 1995), but susceptible newborn mice, with immature immune systems, develop lethal myeloid depression. In vitro, the virus readily kills committed granulocyte–macrophage and erythroid progenitors, as well as pluripotent hematopoietic progenitors, derived from the bone marrow of normal mice (Segovia et al. 1991). Moreover, infection of adult SCID mice, homozygous for the severe combined immunodeficiency mutation, results in a profound leukopenia by the end of the first month and death within 4 months (Segovia et al. 1999). In these animals, the virus causes a novel dysregulation of hemopoiesis, in which primitive hemopoietic progenitors are targeted. This results in severe leukopenia, although circulating platelet and erythrocyte numbers remain stable. In the bone marrow of infected mice, granulocyte–macrophage lineage cells are seen to be markedly depleted, but erythroid progenitors undergo a twofold absolute increase (Segovia et al. 1999), indicating that compensatory mechanisms are mounted specifically by the erythroid lineage in order to maintain effective erythropoiesis. Thus, in immunocompromised adult hosts, complex pathological responses to MVMi infection can emerge that are not apparent in normal mice, a situation that parallels human erythrovirus infections of similarly immunocompromised individuals, as discussed later.

Use as vectors for gene therapy and vaccine delivery

Autonomous parvovirus vectors intended for eventual therapeutic use in humans have been modeled to date on three rodent parvoviruses, MVM, H1, and LuIII, and fall into two main classes. In the first type, the entire coding region of the virus is replaced with transgene encoding sequence, a strategy also employed in the majority of AAV vectors currently in use, discussed below. In the autonomous viruses, these complete coding replacement vectors, mostly based on an infectious clone of LuIII, have been constructed using either the endogenous viral P4 promoter, or a heterologous

mammalian promoter, to drive transgene expression (Maxwell et al. 2002). In the latter case, the only viral components remaining in the vector sequence are the terminal regions, which are used to replicate and package the construct driven by nonstructural and capsid proteins provided in *trans* from a helper plasmid. These vectors have been tested for their efficiency at transducing reporter genes, such as luciferase, into a variety of target cell types. Since helper plasmids can be organized to express VP1 and VP2 species from different parental viruses to construct a single packaged vector, these vectors have been used to map viral tropic determinants to individual structural protein species (Maxwell and Maxwell 2004; Maxwell et al. 1995).

The second type of vector retains the nonstructural gene of the virus and has the transgene substituted for sequences normally encoding the capsid proteins. These capsid replacement vectors, although crippled for the production of progeny, retain the replicative and cytotoxic functions of NS1, and therefore are designed to target cells for transgene expression concomitant with cell destruction. This arrangement also allows for high level transgene expression, both by virtue of being driven off the strongly transactivated P38 promoter and because vector genomes can replicate upon uncoating in the target cell, thus extensively amplifying the P38 transcription templates. In addition to transducing reporter transgenes, vectors of this type have been constructed to express suicide genes, as well as various cytokines, such as IL2, IL4, IP-10, or MCP-3 and other immunomodulatory molecules (Cornelis et al. 2004; Russell et al. 1992; Wetzel et al. 2001; Giese et al. 2002). The rationale behind such vectors is to exploit the natural oncotropism of the parental virus to specifically target transgene expression to tumor cells, with the anticipated result of selectively killing tumor cells or augmenting host antitumor immune responses (Haag et al. 2000; Giese et al. 2002; Cornelis et al. 2004).

The unique life cycle of the autonomous parvoviruses has also been exploited to construct vaccine vectors capable of eliciting lifelong immunity in mice following a single inoculation. By transducing antigen genes into resting lymphocytes, these vectors appear to establish cryptic infection, during which sporadic vector activation primes and continually boosts both humoral and cell-mediated Th1-like immune responses (Palmer et al. 2004).

A consistent problem faced in the successful production of parvoviral vectors has been the generation of contaminating replication competent virus following cotransfection of vector and helper plasmids. This presumably occurs as a result of recombination between NS and capsid gene sequences present in the separate vector and helper plasmids, and considerable effort has been expended to abrogate this phenomenon. Success in this has been achieved by reducing the overlap between the two viral components, and where this is impractical, by altering the DNA sequence underlying the coding sequence through the overlap, by introducing deleterious mutation into one copy of the homologous region, or combinations of these approaches (Dupont et al. 2001; Brandenburger and Velu 2004; Palmer and Tattersall 2000; Brown et al. 2002), such that vector stocks can now be generated with extremely low or undetectable contamination with replication competent virus.

INFECTIONS WITH THE *DEPENDOVIRUS* GENUS

Epidemiology

AAVs were first identified in the mid-1960s as 20-nm particles often found contaminating human and monkey adenovirus preparations. Currently, there are seven recognized human/simian serotypes, of which AAV2, AAV3, and AAV5 were isolated directly from human tissue. More specifically, serotypes 2 and 3 are frequently isolated from multiple tissues in conjunction with adenoviruses, whereas AAV5, the most distantly related member of the group by DNA and protein sequence criteria, has been isolated once, from a condylomatous genital wart, where its natural helper was likely a herpes virus (Georg-Fries et al. 1984). Antibodies against all three are found in about 50 percent of adults, with peak titers occurring between the ages of 10 and 20 (Blacklow et al. 1968a; Georg-Fries et al. 1984). In contrast, AAV4 is probably derived from a simian reservoir, since antibodies to it are very common in nonhuman primates, but are detected at much lower frequencies in humans, with a peak incidence of about 10 percent between the ages of 2 and 5 (Blacklow et al. 1968b). Antibodies reactive to AAV1 are found in a high proportion of both human and simian populations, so that its reservoir is questionable. AAV6 appears to be a hybrid recombinant between AAV1 and AAV2, which can be neutralized with anti-AAV1 sera (Rutledge et al. 1998). The remaining serotypes, AAV7 and AAV8, were isolated from Rhesus monkey tissues. Neutralizing antibodies directed against them are rare in the human population and, when present, are of low titer (Gao et al. 2002).

A surprisingly diverse series of unique AAV proviruses have also been rescued from the tissues of various nonhuman primates with, for example, a single lymph node from one rhesus monkey yielding several quite distinct viruses. This heterogeneity appears to result from AAV sequence evolution within an individual animal due, in part, to extensive homologous recombination between a limited set of coinfecting parental viruses, leading to the formation of swarms of quasispecies (Gao et al. 2003). Interstrain and interserotype genome recombination of this type has also been observed for members of other parvoviral genera

(Lopez-Bueno et al. 2003; Gottschalck et al. 1991), and is likely a common source of diversity in situations where multiple related viruses are able to infect the same host tissue.

AAV-like sequences have also been found throughout the *Mammalia*, commonly being detected in conjunction with species-specific adenoviruses. Recently, avian and snake viruses, AAAV and SAAV, have been cloned and sequenced (Bossis and Chiorini 2003; Farkas et al. 2004). Since they are not associated with pathology, such contaminants are rarely noticed, but are likely ubiquitous throughout the higher vertebrates.

Pathogenesis

AAV infection appears to occur predominantly via respiratory, fecal–oral, and conjunctival routes (Schmidt et al. 1975; Blacklow et al. 1967), although sexual transmission has also been suggested (Han et al. 1996; Georg-Fries et al. 1984). Despite the demonstrable presence of low levels of AAV DNA in many tissues, and their high seroprevalence, no study has convincingly linked AAV to any human disease. Studies designed to investigate the teratogenic potential and tissue distribution of AAVs following transplacental infection in mice and rhesus monkeys similarly failed to suggest pathologic sequelae, and recent interest in these viruses as vectors for gene therapy, discussed below, means that there have now been a large number of detailed animal studies of vector AAVs (predominantly AAV2) in mice, rats, rabbits, and dogs, without identifying reasons for clinical concern. In addition, AAV infection has been shown to inhibit transformation of cells by adenoviruses both in vitro and in animal models in vivo, leading to the suggestion that these ubiquitous viruses might even carry out a form of cancer surveillance in the human population. Results of some serological studies appear compatible with this possibility (Sprecher-Goldberger et al. 1970, 1971; Mayor et al. 1976; Georg-Fries et al. 1984; Han et al. 1996), but the idea still remains controversial.

Use as recombinant vectors for gene therapy

AAV vectors are currently being evaluated in clinical trials for the gene therapy of cystic fibrosis, hemophilia B, and muscular dystrophy (Wagner et al. 2002; Kay et al. 2000; Greelish et al. 1999; Aitken et al. 2001), while many, more preliminary, studies are currently probing their potential use to alleviate a broad range of genetic disorders. The simplicity of the AAVs, their apparent lack of pathogenicity or immune stimulation, and their broad tissue specificities, coupled with their ability to integrate into the host genome and thus achieve stable vertical transmission in dividing cells, render them exceptionally attractive for this purpose. Moreover, they can theoretically be made to integrate preferentially into a single locus in the human genome, on chromosome 19 (19q13-qter), thus limiting the danger of insertional mutagenesis associated with other viral vectors (such as retroviruses) that integrate randomly into host DNA. However, integration into this specific locus requires low level expression of the *Rep* gene, and most AAV vectors explored to date have this sequence deleted in order to avoid its potential cytotoxicity and to increase the genetic capacity of the vector. Thus they resemble the complete coding replacement vectors discussed above for the autonomous parvoviruses. In the absence of *Rep*, vector genomes still integrate with high efficiency into host DNA, but at apparently random sites, that may be the result of insertion into pre-existing double-stranded breaks (Zentilin et al. 2001; Miller et al. 2003).

Since integration generally appears to require ongoing DNA synthesis, it may well be restricted to target cells that are able to enter S phase. This is an important consideration for many gene therapy applications where gene delivery to nondividing cells is required. Surprisingly, however, studies with AAV vectors have shown that relatively stable transgene expression can also be achieved without cell division or integration. Instead, incoming positive- and negative-sense viral genomes appear to become uncoated and rearranged in nondividing cells, where they can be shown to reside as transcriptionally active, monomeric, or concatemeric duplex episomes. It is likely that incoming parental plus and minus strands, derived from separate virions, can anneal during or after uncoating to create these duplexes (Nakai et al. 2000), although various repair strategies can also be invoked, rendering cell division unnecessary for vector persistence and expression. Linear forms of these duplex episomes are commonly observed, particularly in cells with defective repair pathways (Song et al. 2001), but the hyper-recombinogenic nature of the AAV ITR generally results in concatemerization and ultimately circularization of the duplexes, in the absence of either *Rep* or cellular S-phase-dependent DNA replication (Yang et al. 1999).

Recognizing the potential cell cycle independence and transcriptional potency of duplex genomes has also led to the development of 'self-complementary' (scAAV) vectors (McCarty et al. 2001). These have one mutated ITR, which cannot be nicked, flanked by an inverted pair of genomes that are approximately half as long as the wild-type virus and end in a competent ITR, so that progeny are excised and packaged as self-complementary sequences separated by a single, uncleavable, hairpin. As predicted, when used to transduce various nondividing mouse tissues, such as liver, muscle, or brain, these vectors routinely gave more rapid gene expression and higher transduction efficiencies than their single-stranded counterparts. This may, in part, also reflect enhanced genome

survival, since naked single-stranded DNA is likely susceptible to rapid degradation in the host nucleus, making immediate conversion into duplex forms a priority for effective transgene delivery. However, viral capsids exhibit a strict DNA packaging limit, which means that sequences of more than about 5 kb cannot be encapsidated. Since scAAV vectors must carry two copies of the transgene, they have even more limited payloads, of around 2 150 basepairs of nonviral sequence, and hence can only transduce small proteins, ribozymes or anti-sense RNAs.

The transgene size limitation, which might be thought to severely restrict the usefulness of all AAV vectors can, in fact, be overcome by packaging single or multiple exons of large genes, bracketed by intronic sequences, into separate recombinant AAVs. Upon coinfection of the same nucleus, the recombinant genomes can circularize and recombine, creating concatemeric episomes in which the various gene sequences are transcribed in order, and the resulting mRNAs spliced, to yield the desired transgene product (Sun et al. 2000; Yan et al. 2000).

One further potential limitation to the use of AAV vectors is tissue specificity or, more accurately, the levels of therapeutic transgene expression that can be achieved in specific target tissues, since low level expression in most cells is possible with the original AAV2-based constructs. As discussed previously, AAV2 exhibits broad tissue specificity, using a variety of cell surface molecules including heparin sulfate proteoglycan, human fibroblast growth factor receptor and α_v,β_5 integrin as receptors or coreceptors, but it has subsequently become apparent that capsids from other AAV serotypes might prove more efficient for gene delivery to certain tissues. For example, AAV5 particles, which enter by binding to sialic acid residues and polypeptides from the PDGF family, appear to be more efficient at binding and delivering transgenes to cells of the airway epithelia, offering prospects for improved transgene delivery to the lungs (Walters et al. 2001; Rooney et al. 2002), while AAV6 and AAV8 are more efficient than AAV2 in transducing the liver (Grimm and Kay 2003; Gao et al. 2002). In the latter case, the improvement is apparently due to intranuclear uncoating efficiencies, which mean that AAV2 genomes are released slowly and are likely degraded prior to duplex episome formation (Thomas et al. 2004). Efforts to fine-tune the AAV particle to maximize gene delivery to particular cell types has thus led to an explosion of interest in the alternate capsid hypervariable regions available in nature, discussed above, and in the mapping and experimental manipulation of receptor-binding sites on the capsid surface, generating capsids that are targeted to alternate cell surface molecules. Use of such custom-designed AAVs may also ultimately overcome the problem of widespread immunity to the traditional serotypes in the human community, opening the possibility of delivering these rugged, resistant particles by in vivo, systemic routes, rather than the more technically demanding localized or ex vivo applications in current use.

Research on the use of AAV vectors to redress specific clinical conditions is expanding rapidly, although a description of these applications is beyond the scope of this chapter and has been extensively reviewed elsewhere (Carter et al. 2004). Suffice it to mention here that recombinant AAV vectors have been demonstrated to be efficacious in the treatment of many animal disease models, including those for cystic fibrosis, hemophilia, muscular dystrophy, rheumatoid arthritis, and lysosomal storage diseases, as well as several ophthalmic diseases and diseases of the central nervous system. Thus the AAVs appear to offer promise as remarkably versatile and unusually safe gene vectors, while the intense research interest in their biology that this has generated continues to reveal fascinating and unexpected details of their life cycle. With such interest and analysis, it seems likely that a whole family of vectors, fine-tuned to particular tissues and diseases, could rapidly become available.

INFECTIONS WITH THE *ERYTHROVIRUS* GENUS

Epidemiology of B19 virus

The human erythrovirus B19 is distributed globally, and infection is common, so that in Europe, the United States, and Asia around 60 percent of adults have anti-B19 IgG antibodies. It is mostly endemic, potentially emerging at any time during the year, although, in temperate climates, extended outbreaks commonly occur in late winter to early summer. These are particularly apparent in children of elementary school age, but infection continues at a lower rate throughout life. Once infected, immunity generally persists for life, and is a reliable marker of past exposure. In a typical study in England and Wales, anti-B19 IgG was found in 5–15 percent of children between the ages of 1 and 5 years, 50–60 percent of people 16–40 years old, and in excess of 85 percent of people over 70 (Cohen and Buckley 1988).

B19 virus is transmitted primarily via respiratory droplets, and virus can be detected in throat swabs during the week following infection, although exactly where the virus is replicating locally during this time is not known. Transient high titer viremias ensue during which virus can be present at concentrations of up to 10^{12} particles/ml of blood, depending upon the genetic make-up of the patient, as discussed later. However, the incidence of virus in donated blood is generally very low, with only around one in 20 000 to one in 40 000 units containing significant titers of virus, even in an

epidemic season (Cohen et al. 1990), so that infection via transfusion of individual blood units is rare. In contrast, blood products prepared from pools of donated blood can present a problem because B19 is small enough to escape removal by filtration, and is resistant to the heat and solvent treatments traditionally used to inactivate potential microbiological contaminants in such products. As a result, virus from a few viremic blood units appear to have been widely disseminated in blood products such as Factor VIII (Mortimer et al. 1983b), efficiently transmitting B19 virus infection. Thus, the incidence of B19 virus infection among hemophiliacs has historically been high (up to 90 percent), and the probability of infection correlates with the amount of clotting factor received (Azzi et al. 1999; Rollag et al. 1991). Since 2002, producers of plasma derivatives have quantitated and controlled B19 DNA in their source materials, to minimize the risk of transmission.

Diagnosis of B19 infection

Since the virus cannot be propagated effectively in tissue culture, diagnosis of acute infection relies on serologic tests and on the direct demonstration of viral DNA by hybridization or PCR (Zerbini et al. 2002). Antiviral antibodies can be measured with commercial enzyme-linked IgG or IgM capture assays, which usually employ recombinant particles as a target. The presence of IgM antibodies is indicative of recent infection, since these reliably appear within a few days of the onset of infection and persist for 2 or 3 months. Retrospective information on B19 virus infection is obtained by serological survey, with IgG and IgA antibodies typically persisting for life, possibly in response to the reactivation of latent virus. Diagnosis of persistent infection relies on DNA tests, because antibody production may be low or absent in these cases. DNA hybridization using an essentially full-length probe is sensitive enough to detect serum B19 virus levels during acute transient aplastic crisis or in chronically immunosuppressed patients, but the levels of viremia that occur during infection of normal individuals may be missed, as the technique has a baseline detection limit of around 10^6 genomes per ml. The advent of PCR-mediated gene-amplification greatly increased the sensitivity of B19 DNA detection, although this technique readily generates false-positives due to contamination. PCR results can sometimes be difficult to interpret, because low levels of virus routinely persist for months after infection in serum, bone marrow, skin, or synovial tissue from otherwise normal individuals, so that low level detection does not necessarily indicate acute infection. Moreover, the oligonucleotide primers selected may not detect extreme sequence variants of B19, such as the V9/A6 variants discussed later, whereas DNA hybridization does.

Clinical manifestations of B19 virus infection

Many cases of B19 virus infection are asymptomatic. Its most common clinical presentation in hematologically normal children is erythema infectiosum, a mild febrile illness that often presents as a 'slapped cheeks' rash or as a 'lacy' reticulate rash covering the trunk and arms. This common childhood infection was originally called fifth disease, being the fifth in a classic list of childhood rubelliform illnesses, and was well known to pediatricians for the 80 years prior to the recognition of parvovirus B19 as its sole etiologic agent (Anderson et al. 1983, 1984). The rash may be evanescent, and recurrences can be provoked by exposure to sunlight, emotion, heat, or exercise, but it frequently escapes detection in people with dark skin. About 10 percent of EI cases in children have been associated with arthropathy, although retrospective sero-epidemiological studies suggest that an equal number of arthropathies may occur in infected children not presenting with classic EI rash symptoms. Joint pains can persist for months, to a year or more, and are sometimes diagnosed as juvenile rheumatoid arthritis. In adults the classic rash symptoms are somewhat rare, although more prevalent in women than men, and arthralgia and inflammatory arthritis are much more frequent consequences of B19 infection, occurring in about 50 percent of patients. Specifically, nearly two-thirds of female and one-third of male adults experiencing a primary B19 virus infection also experience moderately severe symmetrical polyarthritis involving peripheral finger, wrist, ankle, or knee joints. This effectively means that around 15 percent of new cases of arthritis are the result of B19 virus infections. While arthropathies can sometimes be prolonged and severe enough to fulfill the diagnostic criteria for rheumatoid arthritis, B19 virus infection does not lead to articular erosion, and the arthropathy typically resolves within a few months even in more severe cases.

A characteristic biphasic clinical course of viremia followed by immune complex disease, has been described in both natural and experimental B19 virus infections of normal, otherwise healthy, individuals. In a study of human adult volunteers, viremia was detected 1 week after experimental intranasal infection of seronegative individuals, and was accompanied by a mild, flu-like illness with fever, malaise, myalgia, and itching (Anderson et al. 1985). During the viremic phase, virus is excreted from the respiratory tract, which likely represents the natural mode of transmission. Viremia is coincident with a transient, but absolute, reticulocytopenia and accompanying lymphopenia, neutropenia, and thrombocytopenia. Since the erythrocyte half-life in normal, healthy individuals is several times longer than this period of profound virus-induced bone marrow failure, frank anemia does not develop, and while the

hematological consequences of B19 virus infection are diagnostic, they are not clinically significant. Toward the middle of the second week following infection, virus-specific IgM levels rise, coincident with a fall in detectable circulating virus and the restoration of normal hematological parameters. A brief overshoot of reticulocyte numbers often prefaces this return to normality. IgM, which normally persists for 2–3 months, is followed by IgG, appearing at around 2 weeks after infection and persisting thereafter. The appearance of IgG ushers in the second phase of symptoms beginning 17–18 days after infection, which appear to be the result of immune complex formation. These include both the lacy rashes typical of EI and arthralgia, which normally last for 3–4 days, but can be protracted. Although the major protective immune response to B19 virus is humoral, some studies of cellular immune responses have been reported. These demonstrate that infected individuals mount a robust Th1-like $CD4^+$ T-cell response to viral components, and generate $CD8^+$ cytotoxic T cells that can kill cells pulsed with peptides derived from the B19 NS1 protein sequence (Klenerman et al. 2002).

Ongoing or recent B19 virus infection has also been linked to some forms of idiopathic thrombocytopenic purpura, myocarditis, acute fulminant liver failure accompanied by aplastic crisis, neuropathy, complex regional pain syndrome, neuralgic amyotrophy, and virus-associated hemophagocytic syndrome, although a causal etiology for B19 in these syndromes has not been firmly established. Viral entry and early gene expression can occur in some tissues, such as hepatocytes, that are not susceptible to productive infection. In such cases NS1-mediated apoptosis can sometimes be demonstrated in vitro, and provides a credible biological basis for the clinical observations (Poole et al. 2004). These possible disease associations are discussed in more detail elsewhere (Young and Brown 2004), although the full spectrum of virus-induced disease has still to be unraveled.

The major risk for serious pathologic outcome in normal individuals arises from exposure to B19 virus during pregnancy. A clear connection has been established between B19 virus infection, especially during the second trimester, and the development of non-immune hydrops fetalis, a potentially lethal condition for the fetus that occurs in approximately one of 3 000 pregnancies, and of which 10–20 percent are now believed to be due to B19 virus infection. About 50 percent of pregnant women lack circulating anti-B19 IgG, and thus are potentially susceptible to primary infection, and prospective studies suggest that the risk of transplacental transmission for infected women is about 30 percent, with a 5–9 percent risk of fetal loss. Thus most B19 virus infections during pregnancy do not lead to fetal loss. However, the virus replicates productively in dividing cells of the erythroid lineage, so that transplacental infection of the fetus during the second trimester, in particular, leads to destruction of the rapidly proliferating erythroblasts that are present in erythroid sinuses in the liver at this stage of fetal development. In hydrops cases, fetal infection results in severe anemia, high-output cardiac failure, fluid accumulation and death, although intrauterine transfusion of packed red cells can substantially lower the mortality rate. Fetal B19 virus infection may also cause fetal or congenital anemia, abortion, or stillbirth, although the risk of these occurring as a consequence of a primary B19 virus infection is apparently quite low. Surprisingly, this clear association between fetal pathology and B19 virus has not led, to date, to demand for a protective vaccine. Non-infectious empty recombinant B19 particles have been found to be immunogenic in normal volunteers, and might prevent fetal hydrops if 'at risk,' seronegative women were immunized early in pregnancy. Vaccine-mediated expression of the highly-immunogenic VP1-specific polypeptide, which carries phospholipase A2 activity on the outside of recombinant particles, might possibly be of concern, although such sequences could presumably be mutated or eliminated from a vaccine construct with relative ease.

Since B19 pathogenesis results predominantly from the destruction of rapidly proliferating eythroid precursors, in individuals with genetic defects that result in a shortened erythrocyte half-life and an expanded erythroblast population, anemia develops rapidly, reaches exceptionally high levels, and can require intervention. Thus transient aplastic crisis has been observed as an inevitable consequence of B19 virus infection in patients with single gene defects such as sickle cell anemia, α- or β-thalassemia, hereditary spherocytosis, stomatocytosis, or elliptocytosis, deficiencies in glucose-6-phosphate dehydrogenase, pyruvate kinase, or pyrimidine-5-nucleotidase, as well as in other hematopoietically compromised conditions, such as cold and heat antibody-mediated or chronic autoimmune hemolytic anemia, paroxysmal nocturnal hemoglobinuria, or malarial infection (Heegaard and Brown 2002). The aplastic crisis can be resolved by medical intervention, such as red cell transfusion. Otherwise it will run its course until the humoral immune response clears the virus and erythropoiesis is restored. This type of crisis only occurs once in the life of a patient and, although self-limiting, can cause severe, life-threatening anemia that can precipitate congestive heart failure, cerebrovascular events, and acute splenic sequestration (Smith-Whitley et al. 2004).

Finally, failure to produce neutralizing antibodies to B19 virus can occur in a variety of immunodeficiency states with congenital, iatrogenic, or infectious causes. Typical EI rashes do not develop in such patients, but there are high titers of circulating virus, and its persistence can lead to pure red cell aplasia, with depletion of serum reticulocytes and erythroid precursors from the bone marrow. Pure red cell aplasia of this type has been seen in Nezelof syndrome, an inherited combined immunodeficiency disorder, in patients being treated with cytotoxic chemotherapy or immunosuppressive

drugs, often after organ transplantation, and in patients infected with human immunodeficiency virus (Heegaard and Brown 2002). Immunosuppression can sometimes reactivate latent virus infections, although which tissues serve as the virus reservoir is not currently known. Persistent infection usually responds well to parenteral administration of commercial immune globulin, which invariably contains anti-B19 antibodies because of their prevalence in the donor population, but such intervention commonly leads to the rashes and arthropathy seen in acute infection. More detailed accounts of the clinical outcomes of B19 virus infection are to be found in recent reviews (Heegaard and Brown 2002; Young and Brown 2004).

Genomic polymorphism in B19

The DNA sequence of B19 was first determined from a bacterially cloned copy of a viral genome, B19-Au, isolated in Georgia, USA, from the serum of a child with homozygous sickle cell disease undergoing transient aplastic crisis (Shade et al. 1986), and this has become the reference sequence. Since that time a large number of isolates have been sequenced, or partially sequenced throughout the world, and, until 1999, all genomes appeared highly conserved. In general, they showed less than 2 percent nucleotide divergence, spread throughout the entire virus although certain regions, such as the *NS* gene, were particularly conserved. Minor antigenic and genetic differences between isolates were sometimes observed, manifest as differences in monoclonal antibody specificity, restriction fragment polymorphism, or single-stranded conformational polymorphism, but these did not appear to correlate with differences in the tissue specificity of the virus or its disease spectra. However, B19 diagnosis commonly relies on the identification of viral DNA by PCR, and this test inevitably favors the detection of conserved genomes.

Accordingly, in 1999, the blood of a French child suffering from transient aplastic anemia was found to contain a new type of virus, called V9, which eluded detection by the then-current PCR technique (Nguyen et al. 1999). At the nucleotide level, the isolate was more than 11 percent divergent from published B19 sequences (Heegaard et al. 2001), although certain regions were relatively conserved and allowed the design of new PCR assays using primers that would detect both V9 and B19 DNA. An extensive prospective study conducted in France between 1999 and 2001 subsequently revealed that V9-related viruses circulate beside B19 viruses at a significant frequency (11.4 percent) in the French population. Such genomes were surprisingly absent from large groups of North American and Danish samples analyzed at that time, suggesting that such variants might be epidemiologically linked to a particular geographic area, in this case France. An extraordinary aspect of V9 is that, despite its DNA sequence divergence, it is 96–97 percent homologous to B19-Au at the protein level. Thus, the great majority of its nucleotide changes are silent mutations that do not affect the amino acid sequence of the viral proteins, which therefore react with most anti-B19 antibodies (Heegaard et al. 2001). Another new variant, designated A6, has since been isolated in America, which is 88 percent similar to B19 virus and 92 percent similar to V9 at the nucleotide level (Nguyen et al. 2002), and an essentially similar mutant was detected in Finland, where it was called K71 or Lali (Hokynar et al. 2002). At present there is no established explanation for the emergence of these hypermutated variants, however, relationships between specific genotypic variants and specific disease states have been looked for, but not found.

In vitro cellular correlates of B19 pathology

Parvovirus B19 binds to the blood group P antigen, a neutral glycolipid called globoside that is expressed predominantly on human erythrocytes and erythroid progenitors. This functions as a productive cell surface receptor for B19, consistent with its observed tropism (Brown et al. 1993). In the human population, about one in 200 000 individuals genetically lack P antigen, and show no serologic evidence of past B19 virus infection. Bone marrow cultures derived from these individuals fail to support the growth of B19 virus in vitro, even at a high multiplicity of infection (Brown et al. 1994), indicating that the presence of P antigen is necessary for infection. However, it may not be sufficient. Thus, while P antigen is present on a number of cells such as fetal myocytes, megakaryocytes, endothelial cells, as well as the hepatocytes discussed previously, these cell types do not appear to be permissive for B19 replication, suggesting that additional factors may be required for complete replication. Some studies indicate that entry coreceptors, such as β-integrins, may be required, but intracellular permissivity factors are also indicated, since in culture many nonpermissive cells appear to support early, but not late, transcription (Liu et al. 1992). This abrogates capsid protein synthesis, but still allows expression of the potentially cytotoxic NS1 molecule of the virus (Moffatt et al. 1998; Ozawa et al. 1988), which in vitro can be shown to induce caspase-mediated cell death (Poole et al. 2004).

Development of a cell culture system that supports productive B19 replication has been extremely difficult, and at present, there is no animal model for the virus. In primary human bone marrow cultures, B19 virus inhibits colony formation by late erythroid progenitors and the more primitive burst-forming erythroid progenitors, while leaving differentiation of myeloid precursors unperturbed (Mortimer et al. 1983a). It appears from both in vivo and in vitro studies, that the pluripotent erythrogenic stem cell is resistant to virus infection,

while in the presence of erythropoietin, B19 virus will grow in later progenitors derived from human bone marrow, fetal liver, and peripheral or umbilical blood. Infection of such erythroid precursors in vitro with B19 leads to a cytopathic effect characterized by the presence of giant pronormoblasts, which appear to be equivalent to the 'lantern cells' that can be observed in vivo in the bone marrow of patients undergoing B19-associated transient aplastic crisis. These cells exhibit large eosinophilic nuclear inclusion bodies and cytoplasmic vacuolization, and electron microscopy reveals nuclei with marginated chromatin that contains virus particles. While such explanted cells cannot be maintained in long-term culture, B19 virus has also been shown to propagate in a small number of permanent cell lines of megakaryoblastoid and erythroleukemic origin, although net synthesis of virus has not been achieved in these systems (Heegaard and Brown 2002).

An infectious plasmid clone of B19 has recently been constructed, and shown to give rise to detectable levels of infectious progeny when transfected into the erythropoietin-responsive cell line UT7/Epo-S1 in vitro (Zhi et al. 2004). It seems likely that mutational analysis of this clone should allow rapid progress in understanding the molecular biology of this ubiquitous human fellow traveler, which will hopefully also inform our understanding of B19 pathology. At the core of this pathology is the destruction of rapidly proliferating erythroid precursors, which derives from the narrow tissue tropism of the virus and its absolute dependence on the presence of rapidly dividing cell populations. Thus, despite the organizational differences between individual genera in the *Parvovirinae*, the pathogenic potential of B19 follows the same underlying biological principles that determine disease throughout the autonomously replicating viruses from this family.

ACKNOWLEDGMENTS

The authors thank Zoltan Zadori and Peter Tijssen for the phylogenetic analysis presented in Figure 1, and Michael Chapman for the parvovirus images shown in 21.2. The authors were supported by NIH grants CA29303 and AI26109 from NCI and NIAID, respectively.

Adenoviruses

WILLIE RUSSELL

Properties of the viruses	1	References	8
Clinical and pathological aspects	5		

The term adenoviruses was coined in 1956 (Enders et al. 1956) to describe infectious agents that had been isolated from human adenoids (Rowe et al. 1953) and were similar to those associated with outbreaks of respiratory disease in military recruits (Hilleman and Werner 1954). The virus family was initially characterized in terms of crossreactivity in serological tests and it soon became apparent that adenoviruses sharing this common antigen were to be found in a wide variety of species. Fundamental studies on adenoviruses and their interactions with their host cells were greatly stimulated by the discovery by Trentin and his colleagues (Trentin et al. 1962) that some human adenovirus serotypes could induce tumors in hamsters. However, later studies could not demonstrate any association with human tumors. This finding, coupled with the observations that adenoviruses did not appear to be associated with any serious morbidity and that they could readily be grown in a wide variety of cell lines, led to their being used extensively as model laboratory systems to study the molecular basis of virus infection (for a review, see Russell 2000).

PROPERTIES OF THE VIRUSES

Classification

Adenoviruses have been characterized primarily on the basis of a common genus-specific antigen and a very characteristic morphology. Serotypes are classified by their ability to induce specific neutralizing antibodies. A serotype can therefore be defined as one that either exhibits no cross-reaction in neutralization with other animal typing antisera or shows a homologous:heterologous neutralization ratio of >16 (in both directions). For ratios of 8 or 16, a serotype assignment is made on the basis of other serological, biophysical, or biochemical differences.

Four families are now recognized using phylogenetic calculations based on distance matrix or parsimony analysis coupled with protein or DNA alignment on any suitable gene. These are the *Mastadenoviridae* isolated from mammals (bovine, canine, caprine, equine, human, murine, ovine, porcine, simian); the *Aviadenoviridae* isolated from birds (duck, fowl, goose, pheasant, turkey); the *Atadenoviridae* isolated from some bovines, birds, and snakes, and the *Siadenoviridae* isolated from frogs, fish, and turkeys, giving a total of at least 170 different viruses. However, the most intensively studied adenoviruses are the 51 serotypes isolated from humans (Russell and Benko 1998; Benko et al. 2000).

Morphology and structure

The virions are non-enveloped, 80–110 nm in diameter and their capsids have icosahedral symmetry (Figures 1 and 2). They have 240 nonvertex capsomeres (hexons) 8–10 nm in diameter and 12 vertex capsomeres (pentons). The pentons consist of penton bases and attached knobbed fibers, each in close association with a ring of five hexons; these are termed the peripentonal hexons. Each of the penton bases has one (or occasionally two) fibers that protrude 9–30 mm from the capsid. Several other structural polypeptides (IIIa, VI, VIII, IX) are associated with the capsid and serve to cement the hexons and to link the capsid to the core (Stewart et al. 1993). The latter consists of a double-stranded DNA genome with a covalently linked terminal

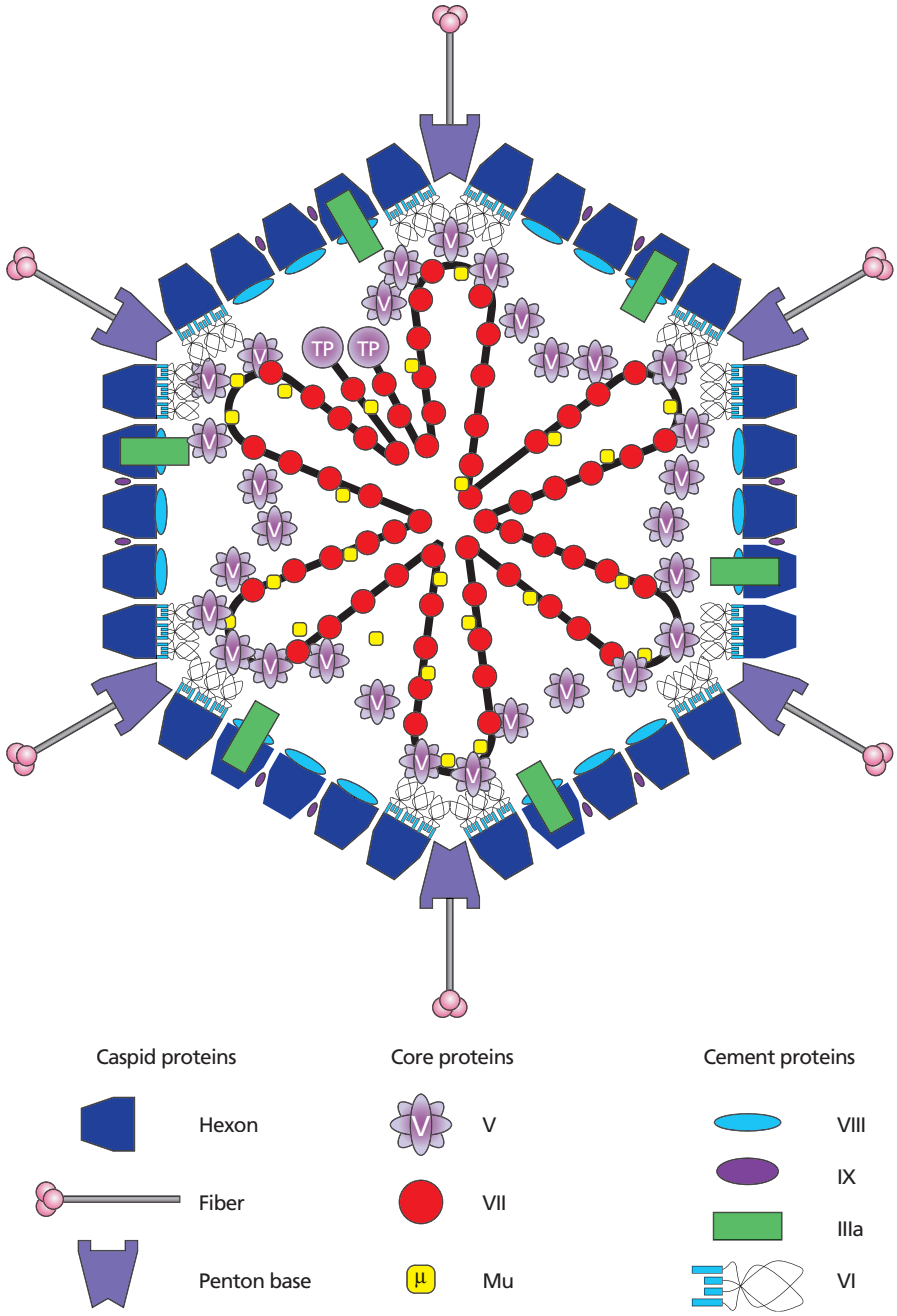

Figure 1 *Structure of adenovirus. The locations of the capsid and cement components are reasonably well defined. By contrast, the dispositions of the core components are largely conjectural. (Redrawn from Figure 1 of Russell (2000), with permission of the Society for General Microbiology)*

protein (TP) in tight association with three other polypeptides, V, VII, and mu (Figure 1). The structure of this nucleoprotein core has not been established and the core polypeptides are shown in hypothetical locations in Figure 1. The major capsid protein, the hexon, has been crystallized and its three-dimensional structure shown to be based on a composite of three identical and interlocking polypeptide chains that form a triangular tower superimposed on a pseudohexagonal base (Stewart and Burnett 1995). The fiber knob has also been crystallized and a structure obtained (van Raaij 1999). The virus is stable between pH 6.0 and 9.5, is resistant to chloroform, ether, and fluorocarbons, and on heating to 56°C disintegrates, releasing core structures (Russell et al. 1967).

On examination by electron microscopy, some preparations of adenoviruses are seen to be contaminated by small round adeno-associated viruses (Figure 2). These ssDNA parvoviruses belong to the family *Dependoviridae* (see Parvoviruses) and require adenoviruses (or herpesviruses) for their replication.

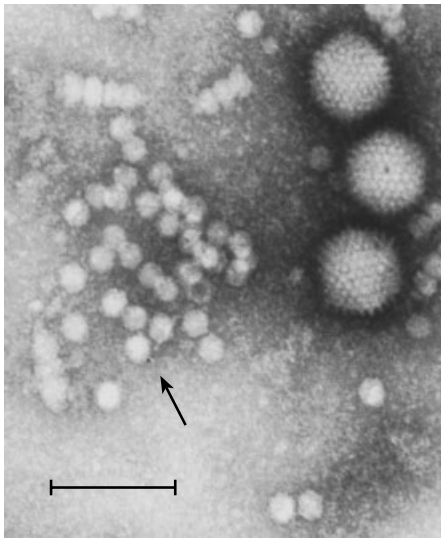

Figure 2 *Three adenovirus virions with dependoviruses (arrowed), negatively stained with phosphotungstic acid. Scale bar, 100 nm.*

Genome structure and function

The adenovirus virion contains a single linear dsDNA genome of approximately 20–25 kb. A virus-coded terminal protein is covalently linked to the 5′ end of each DNA strand. The genome of the prototype human adenovirus type 2 has 35 937 bp and contains inverted terminal repeats (ITR) of 103 bp. A large number of other adenoviruses have been completely sequenced and all contain ITRs, but of variable length. Viruses replicate in the nuclei of a wide variety of cells of the species that they normally infect, giving a characteristic pattern of nuclear staining. Some adenoviruses can infect cells of other species; such infections are often abortive and, under suitable conditions, may give rise to morphological transformation and thereby provide model systems for oncogenesis (see below).

Entry of virus is by attachment of the fiber via its knob (Figure 1) to cell receptors, the major one being termed coxsackie adenovirus receptor (CAR) (Bergelson et al. 1997). Some human serotypes can also utilize sialoglycoproteins as receptors (Arnberg et al. 2002). It is interesting that human adenovirus 41 has two fibers and only one recognizes the CAR. Since this virus readily infects cells of the gastrointestinal tract and produces diarrhea, it seems likely that one of the fibers may adsorb to enterocytes. Internalization of the virus particles with the penton bases interacting with cellular integrins via clathrin-coated vesicles is followed by transfer into endosomes. Thereafter, the virus capsid is partially disrupted by a virus-coded protease (Greber et al. 1996) and then transported to the nuclear pores where the virus DNA, probably in close association with the core components, is delivered into the nucleus and becomes attached to the nuclear matrix via the viral terminal protein (Fredman and Engler 1993). A series of nuclear and nucleolar perturbations then follow in which transcription and virus DNA replication are prominent (see Russell and Matthews 2003)

The adenovirus genome becomes available for transcription using cellular transcription factors that are abundant in the nuclear matrix. This process is well regulated and involves the synthesis of four major classes of ‘early’ transcripts (E1–E4), minor ‘intermediate’ transcripts, and late transcripts (L1–L5). The last are initiated at the ‘major late promoter’ and, allied to a tripartite leader formed by a series of splicing events, drive the synthesis of most of the structural proteins; the ‘early’ transcripts are also subject to complex splicing mechanisms. The overall nature of transcriptional regulation has not been completely elucidated but it has been suggested that as well as splicing control, the topology of the virus genome can be affected by the core proteins limiting template availability for transcription. After synthesis of the early transcripts and synthesis of ‘early’ proteins [e.g. virus DNA-binding protein (DBP)], further alterations in template topology and availability could permit virus DNA replication, thereby creating new progeny templates for late transcription (see Figure 3). However, all these transcriptional events are subject to other regulatory controls of a quite complex nature (see Russell 2000).

Virus DNA replication

Adenovirus DNA synthesis is initiated at either end of the linear double-stranded DNA and three ‘early’ viral proteins are required together with at least three cellular proteins. The initial event involves the interaction of one of the early proteins, the precursor of the terminal protein (pTP), with specific terminal DNA sequences followed by association with another early protein (polymerase) and then the formation of an ester bond between the phosphate of dCMP (C being the first nucleotide in the DNA sequence) and a serine residue in pTP. This can then function as a primer to extend a progeny DNA strand using one strand of the virus DNA as template; this process utilizes the viral polymerase and the cooperation of three other proteins, two of them cellular. The latter (NF1 and NF3) are also transcription factors and bind to specific sequences in the viral DNA, presumably facilitating the formation of the initiation complex. The other early virus protein, the DBP, also plays a role in virus DNA initiation as well as facilitating strand separation during elongation and binding to the progeny DNA strands. A third cellular protein (NF2) seems to be required for complete elongation of the progeny strand and appears to be equivalent to cellular topoisomerase I. Synthesis of the second strands takes place after that of the first strands and the formation of

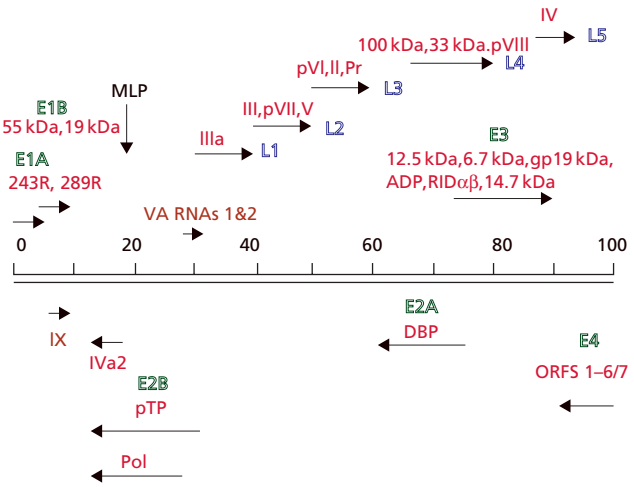

Figure 3 *Transcription of the adenovirus genome. The early (E) transcripts are outlined in green. The components of each cassette are named in a conventional manner, e.g. some are merely numbered as open reading frames (orfs) and others defined by their molecular weights or by the number of amino acids. The late (L) transcripts are outlined in blue. MLP refers to the major late promoter. The transcripts IX, IVa2 and the VA RNAs are transcribed late but independently of the MLP. The VA RNAs are not translated and play a significant role in combating cellular defense mechanisms. Arrows indicate the direction of transcription. (From Figure 2 of Russell (2000), with permission from the Society for General Microbiology.)*

a 'panhandle' structure formed by the interacting ITRs, thus allowing replication by a similar mechanism – for a recent review see Liu et al. (2003).

Polypeptides and maturation of the virion

Translation of the adenovirus transcripts begins quite early in infection and continues uninterrupted in concert with virus assembly for up to about 40 hours when both cellular and virus protein synthesis are shut off. In tissue culture systems this process is very inefficient and normally a vast excess of virus capsid proteins are made.

A number of adenovirus genomes have been completely sequenced and the dispositions of the polypeptide genes have been mapped. While there are some differences in the number and position of the polypeptides on the genome across the adenovirus family, on the whole there is good conservation of genome structure. It is also apparent that, by virtue of its splicing mechanisms, the genome makes efficient use of template information and synthesizes about 40 different polypeptides, 13 of these being incorporated into the mature virus particle (see Figure 1). Three of the nonstructural proteins synthesized early in infection are involved in virus DNA replication and are derived from the E2 transcription region. The remainder of these 'early' nonstructural proteins seem to function as modulators of the host cell, so that virus transcription and replication are favored, and to counteract the host immune response. It should be noted that not all the 'late' genes are structural: a major product of ca. 100 kDa seems to function as a chaperone for other structural proteins but is not itself encapsidated. Two other gene products, polypeptides IX and IVa2, are regulated independently of the others and, whereas IX is clearly a structural component, the evidence that IVa2 is structural is not very strong.

The maturation of adenovirus is intimately linked to the functioning of the adenovirus gene-coded 23 kDa protease (Webster et al. 1989). This enzyme is synthesized late in infection and performs cleavages, leading to maturation, on six virus structural proteins: IIIa, pVI, pVII, pVIII, pTP, and protein p-mu. The enzyme is a cysteine protease of an unusual subset and recognizes consensus sequences (M,L,I)XGX↓G or (M,L,I)XGG↓X (Webster et al. 1989). It also has the remarkable characteristic of requiring for activation a disulfide-bonded dimer of an 11-residue peptide derived from the C terminus of polypeptide pVI (Webster et al. 1993). Investigations have also shown that, in an in vitro assay, pVI will bind to the principal capsid component, the hexon, but binding is very significantly enhanced whenever pVI is cleaved by the protease (Matthews and Russell 1995). This suggests that a primary maturation event is the interaction of adenovirus protease with pVI in a 'young' virion, i.e. that formed by the introduction of virus DNA and associated proteins into the precapsid. The protease is then activated, allowing cleavage of pVI to VI accompanied by tight binding to hexons, probably also with conformational changes leading to the proteolytic cascade that marks virion maturation. The encapsidation process is also governed by the presence in the virus DNA of a packaging sequence at the conventional left end and seems to involve the binding of the virus-coded IVa2 protein (Zhang et al. 2001).

These events take place in the cell nucleus and many thousands of virions can be assembled, often in

paracrystalline arrays. In some cells the assembly process seems to be inefficient, so that many structural proteins (mostly capsomers) are made in excess and these can also form paracrystalline structures. Release of the virus results from permeabilization of nuclear membranes largely mediated by one of the nonstructural virus proteins (Tollefson et al. 1996). Abortive infections by adenovirus can occur whereby some of the early genes are expressed and, given the appropriate circumstances, can lead to morphological transformation and tumor formation in some animal model systems. There are also indications that adenoviruses can persist in vivo, engendering life-long immunity – see Lukashok and Horwitz (1998).

Antigens

As noted above, adenoviruses can be characterized on the basis of their crossreacting (or 'group') antigens and further subdivided into serotypes based on neutralization. Most adenoviruses can hemagglutinate rat or monkey cells and this characteristic has been used to subgroup the human adenoviruses and to confirm serospecificity (Table 1). These subgroups also correlate to some extent with clinical patterns (see Table 2) and with the ability to induce tumors in hamsters. The utility of these serological assays has undoubtedly been enhanced by the relatively large amount of antigens (mostly associated with the capsomers) released during infection.

The serotype-specific antigens are located on the surface of the virions and are responsible for the formation of the neutralizing antibodies. Both hexons and fibers can induce neutralizing antibodies, whereas pentons and fibers appear to function in hemagglutination. The hexon serotype-specific antigens can be assigned to the tower regions of the structure whereas the genus-specific antigens seem to reside on the basal surfaces of the hexons at the region where they interact with each other and with polypeptide VI.

A range of hexon and fiber monoclonal antibodies has been prepared and has been instrumental in defining type and group specificities as well as antigenic relationships both within and between subgroups (Watson et al. 1988).

Classification of adenoviruses by serological procedures was later supplemented by restriction enzyme analysis of virus DNA extracted from infected cells. By using a defined and limited range of restriction enzymes, patterns characteristic of adenovirus serotypes can be obtained; furthermore, this approach allows further analysis of serotypes into defined 'genotypes' – see Kajon et al. (1996). However, with the increasing availability of sequence data it has become possible to apply phylogenetic analyses to adenovirus classification and this has now become the method of choice and can even be applied in the absence of isolation of the infectious virus (e.g. Benko et al. 2002).

CLINICAL AND PATHOLOGICAL ASPECTS

Adenoviruses are widespread in many species and can be isolated from both sick and healthy individuals. Antibodies can be detected in almost all humans, reflecting infection early in childhood and possibly lifelong persistence in adenoid and lung tissues. Mortality and morbidity associated with infection are relatively low and undoubtedly ensure that the virus retains its biological niche. Nevertheless, pneumonia and gastrointestinal disease can be serious especially when immunological status is impaired – as is the case for patients with the acquired immunodeficiency syndrome (AIDS) and those undergoing transplantation procedures.

Clinical manifestations

Adenovirus infections are mostly asymptomatic but may be associated with diseases of the respiratory, ocular,

Table 1 *Subgrouping of human adenoviruses: hemagglutination and oncogenicity*

Subgroup[a]	Serotypes	Species giving hemagglutination titers	Oncogenicity in hamsters
A	12, 18, 31	Rat (incomplete)	High
B	3, 7, 11, 14, 16, 21, 34, 35	Monkey	Weak
C	1, 2, 5, 6	Rat (incomplete)	No
D	8, 9, 37	Rat, mouse, human, guinea pig, dog	No
	10, 19, 26, 27, 36, 38, 39	Rat, mouse, human	
	13, 43	Rat, mouse, human, monkey	
	15, 22, 23, 30, 44–47	Rat, mouse, monkey	
	17, 24, 32, 33, 42	Rat, mouse	
	20, 25, 28, 29	Rat, monkey	
E	4	Rat (incomplete)	No
F	40, 41	Rat (atypical)	No

a) The subgrouping is based on a variety of criteria: differential hemagglutination, fiber length, oncogenic potential in rodents, percentage DNA homology, G+C content of viral DNAs, and the ability to recombine with other members of the subgroup (see Horwitz 1990 for a more detailed explanation). Table derived from information presented by Hierholzer (1992) and Horwitz (1990).

Table 2 *Subgrouping of human adenoviruses: association with disease*

Syndrome	A	B	C	D	E	F
Upper respiratory illness	. . .	All	. . .	. . .	. . .	. . .
Lower respiratory illness	. . .	3, 7, 21	. . .	. . .	4	. . .

Sexually transmitted disease[b]	. . .	. . .	2	19, 37	. . .	. . .

a) Gastroenteritis is due predominantly to types 40 and 41 and to a lesser extent to types 2 and 31.
b) Penile and labial ulcers and urethritis. Table derived mainly from information presented by Hierholzer (1992) and Horwitz (1990).

and gastrointestinal systems (Table 2). Volunteers have been infected by rubbing virus into their conjunctivae or by administration of aerosols but, in general, it has been difficult to demonstrate unequivocally that the viruses cause disease, because they can be found in apparently normal tonsils and adenoids. Infections with human adenovirus serotypes 1, 2, 3, 5, and 6 usually take place in early childhood, giving mild respiratory infections. It has been suggested that these infections may well induce sufficient immunological defenses to modulate the progress of subsequent infections by related serotypes. The importance of adenoviruses in pediatric respiratory tract infection is not as great as that of respiratory syncytial and parainfluenza viruses, and it has been estimated that only about 5–10 percent of pediatric respiratory infection can be attributed to them. Nevertheless, acute respiratory infections occur in children and in immunocompromised children disseminated disease (with some mortality) has been reported, particularly in association with types 3 and 7 and even with type 5 (Munoz et al. 1998). Adenoviruses have also been reported to account for 10 percent of pneumonia in children and are a particular threat in developing countries where there is malnutrition and exposure to measles (for a review see Wadell 2000). Respiratory infections may also be important in military recruits, of whom 30–80 percent may become infected, usually with types 4, 7, 14, or 21; up to 20 percent may require hospitalization. This morbidity had such an effect on training schedules that the US government invested heavily in the development of appropriate vaccines. Explosive outbreaks have also been reported in boarding schools and other institutions where young people live in close association.

Pharyngoconjunctival fever is another well-defined clinical syndrome that is characterized by conjunctivitis, fever, pharyngitis, and enlargement of the adenoids. This is usually associated with types 3, 4, and 7 and can be disseminated via poorly chlorinated swimming pools. Epidemic keratoconjunctivitis ('shipyard eye') was first associated with adenovirus type 8, but other serotypes (e.g. 19 and 37) have also been incriminated in this syndrome. Adenovirus type 11 has been associated with hemorrhagic cystitis in school-age boys and cases have been reported after renal and bone marrow transplantation. Adenoviruses are often a serious problem in patients undergoing immunosuppressive treatment and in AIDS patients. Indeed, a range of new serotypes was first isolated from patients with AIDS (e.g. the latest serotypes 50 and 51 – see Schnurr and Dondero 1993; De Jong et al. 1999), suggesting that persistent long-term infection by adenoviruses kept under control by immune surveillance may be the usual situation.

The role of adenoviruses in gastrointestinal disease is, however, much more important; infection of the colon and the gut can cause severe diarrhea and acute gastroenteritis, especially in developing countries. Serotypes 40 and 41 seem to be mainly responsible for these outbreaks and the viruses can be detected in large numbers in the feces of infected children. Up to 15 percent of children hospitalized with acute gastroenteritis can be attributed to these enteric adenoviruses, second only to rotaviruses as the cause of infantile viral diarrhea. It is interesting that fecal shedding of adenoviruses appears to be a characteristic of all serotypes, but types 40 and 41 are particularly associated with enteric disease. The tropisms of these serotypes differ from those of others in that they fail to infect standard tissue cell lines such as HeLa and HEp-2 and require primary human kidney cells or the adenovirus-transformed human cell line 293 (Graham et al. 1977).

Adenovirus infections are common in many animal species. As in humans, they appear to be mostly asymptomatic and there is therefore a paucity of information on the mode and mechanics of virus transmission. There is some evidence that sometimes a virus that is asymptomatic in its natural host can produce disease in other

species. Thus epidemics of reduced laying and production of soft shell or shell-less eggs in some chicken flocks have been attributed to a duck adenovirus (EDS'76). As in humans, most of the animal adenoviruses can be isolated from the tissues of healthy animals and there is very little evidence that they cause disease in wild populations. Nevertheless, two serotypes of canine adenovirus (CAdV) do seem to cause different patterns of disease: CAdV-1 is responsible for infectious canine hepatitis and, along with CAdV-2, is among the viruses causing the 'kennel cough' syndrome. Epizootic infections with CAdV-1 in foxes, bears, wolves, coyotes, and skunks have also been reported. CAdV-2, on the other hand, seems to be confined to infections of the canine respiratory tract (reviewed by Russell and Benko 1998).

Epidemiology

Adenovirus infections are widespread and appear to be transmitted primarily by the fecal–oral rather than the respiratory route. The latter may, however, be more important for the lower numbered human serotypes. Seasonal variation of adenovirus epidemics is well recognized. Most outbreaks of pharyngoconjunctival fever in school-age children occur in summer; by contrast, epidemics in military recruits appear almost exclusively in the winter.

Infections with adenoviruses occur early in life: by 5 years of age almost all children have been infected by at least one, generally a low-numbered serotype. The epidemiology of individual serotypes has been elucidated in more detail by using restriction enzyme analysis to distinguish between isolates of type-specific viruses. In this way, the provenance of particular genotypes within these serotypes (e.g. Ad8, Ad19, Ad37) can be traced in the population. Such studies suggest that some genotypes may be associated with increased morbidities. They also indicate that multiple persistent infections probably provide opportunities for recombinational events (for a review see Wadell 2000).

Pathogenesis and pathology

In susceptible cells, adenoviruses cause early rounding and aggregation, followed by the appearance of characteristic basophilic nuclear inclusions. In organ cultures of human embryonic nasal mucosa and trachea, they infect and destroy the ciliated epithelium and it is likely that the same process occurs in vivo. Although organs outside the respiratory tract may be affected (eg liver and kidney) during severe adenovirus infection, replication rarely occurs unless the patient is immunologically compromised.

Considerable progress has been made in our understanding of adenovirus pathogenesis by studies in cotton rats (*Sigmodon hispidus*). These animals are susceptible to intranasal infection with human adenovirus type 5 (and other members of subgroup C), developing pulmonary histopathology very similar to that in human cases. The virus replicates in the bronchiolar epithelial cells, but in situ hybridization also shows early gene expression in macrophages/monocytes and in both alveoli and hilar lymph nodes. It is interesting that only early gene expression is needed to produce the pathology, of which there is an 'early' and a 'late' phase (for a review see Ginsberg 1999).

It is now well established that at the molecular level host pathology is largely governed by the success or otherwise of the ability of the invading virus to evade the host protective responses. In general, host cells have a range of strategies to combat infection: these can be considered as innate and adaptive. In the first category can be included the natural antimicrobial peptides (defensins) released by epithelial cells. Some tissues on receiving the appropriate signal (e.g. when a virus particle interacts with the plasma membrane) are able to release multiple chemokines which in turn recruit neutrophils and invoke an inflammatory response. One key factor in regulating the innate response is the activation of the cellular transcription factor NFκB (Dixit and Mak 2002).

Interferons are an important component of the innate response but adenoviruses are generally refractive to interferons mainly because their early gene products can down-regulate components of the cellular pathways that are activated by interferons. Another mechanism that can be utilized by cells under attack is to commit suicide by switching on their apoptosis circuits. A key regulator of these events is the tumor suppressor p53 which controls both cell cycle arrest and apoptosis (Ljungman 2000). Once again, early virus gene products can interfere with these pathways in a variety of ways (for a review see Russell 2000).

Immune response

The response to adenovirus infection by the immune system is efficient and well orchestrated and undoubtedly accounts for the generally low levels of morbidity. Cell-mediated responses are mounted but the virus can counteract most of these by means of products expressed from the early genes. For example, one of these is an abundant transmembrane protein which binds class I major histocompatibility complex (MHC) antigens and retains the complex in the endoplasmic reticulum. Since surface expression of class I antigens complexed with viral peptides is required for recognition and lysis by virus-specific cytotoxic T cells (CTL), this strategy effectively thwarts the host CTL response. Although CTLs are one means by which the host eliminates virus-infected cells, there are others, involving secretion of cytokines such as tumor necrosis factor (TNF) and other early virus gene products are able to interfere with these pathways.

The proliferative T-cell responses in humans are mediated by $CD4^+$ T cells, and structural proteins appear to be important targets. In addition, proliferative responses to the uncommon adenovirus type 35 (Ad35) have been found in individuals without serological evidence of previous Ad35 infection. These findings suggest that $CD4^+$ cells recognize conserved antigens and that this may play a role in modulating infections with a range of serotypes. The mechanisms of the cellular and humoral immune responses have been of intense interest following the development of recombinant adenovirus constructs as vehicles for gene therapy. However, expression of the correct gene is quite often only transient and this seems to be associated with the development of an effective host immune response. For a review of the characteristics of early gene products and adenovirus vectors see Russell 2000.

Diagnosis

Human adenovirus infections are ideally diagnosed by isolation of virus from appropriate clinical samples in a variety of sensitive indicator cell cultures such as HeLa, HEp-2, KB, or A549. The use of the 293 line of adenovirus-transformed cells (Graham et al. 1977) also facilitates the isolation of the enteric adenoviruses 40 and 41. Rounding and aggregation of cells appear after incubation for 1–4 weeks. The culture fluids containing virus and soluble antigens can be used to characterize the virus further by neutralization and by hemagglutination inhibition assay (see Table 1).

More sensitive and rapid tests have been introduced over the last few years and have found a place in many diagnostic laboratories. They include, for example, enzyme immunoassays and immunoelectron microscopy. Characterization of serotypes by restriction enzyme mapping has also been of significant value (see above). However, the most sensitive technique for virus recognition is the polymerase chain reaction (PCR) using primers based on those base sequences that are common to the genus. A number of different primers have been utilized. This technique can be exquisitely sensitive and be used where cellular techniques have not been successful (e.g. in blood and urine samples) (Echavarria et al. 1998). PCR has also been utilized successfully for environmental detection using air filters (Echavarria et al. 2000).

Current developments are using 'real-time' PCR to obtain more semiquantitative data (Houng et al. 2002). The advent of automatic sequencing has added yet another dimension to diagnosis and should assist in more precise characterization of isolates.

Control

Vaccination has been used with some success to control epidemics of adenovirus infection in military recruits and in bovines. Both inactivated and live adenovirus vaccines have been used in military recruits but live vaccines proved more effective in reducing the incidence of disease. Initial development concentrated on type 4 serotype; unattenuated virus was fed to volunteers in enteric-coated capsules to establish an asymptomatic infection in the lower alimentary tract. The virus induced moderate amounts of neutralizing antibody and, more importantly, did not spread to susceptible contacts. The type 4 vaccines grown in human diploid cells have been given to several hundred thousand military recruits with no untoward side-effects and with a significant reduction in morbidity. A triple vaccine incorporating types 4, 7, and 21 was also successful (Takafuji et al. 1979). Vaccine production ceased in 1995 and by 1999 the supplies had been exhausted and, not surprisingly, adenovirus respiratory diseases are again becoming a problem in military recruits. Vaccines have not, in general, been considered for use in the general population since the cost of development, production, and control would be quite substantial and would appear not to be commensurate with the risk of clinically significant infection. However, this position may change with the increasing use of transplantation therapies.

There has been one report of the use of normal human immunoglobulin for combating disseminated adenovirus infection (Munoz et al. 1998) and also one report of the successful use of ribavirin (Arav-Boger et al. 2000) but, as yet, there have been no other signs of a substantiated effective antiviral chemotherapy.

BACKGROUND

Papillomaviruses are small double-stranded DNA viruses that induce warts on cutaneous and mucosal surfaces in many vertebrates, including humans. The infectious nature of warts was shown unequivocally in 1907 by the Italian physician Ciuffo, who demonstrated person-to-person transmission of lesions by cell-free wart filtrates. Seminal aspects of the biology and, in particular, the oncogenic potential of this group of viruses were demonstrated by Richard Shope in the 1930s, when he showed that the cottontail rabbit papillomavirus (CRPV) was the etiologic agent in cutaneous papillomatosis in the rabbit. The use of the electron microscope as a research tool in biology in the 1950s revealed papillomaviruses to be the infectious agent for human warts, but although the viruses were known in 1964 to have a genome consisting of circular double-stranded DNA, biochemical characterization of their proteins was slow because no tissue culture system for virus growth was available. Virus particles had to be obtained from clinical lesions, and the amount of virus in warts was highly variable; thus virions were abundant in plantar warts but sparse in laryngeal and genital warts. These handicaps severely limited immunologic and virologic studies, and until the mid-1970s the general view was that there was only one human papillomavirus (HPV), and that tissue location rather than virus type dictated the morphology and behavior of the clinical lesions at a specific epithelial surface.

The advent of molecular cloning and recombinant DNA technologies in the 1970s resulted in a complete reversal of this view, revealing an astonishing plurality of both animal and human papillomaviruses. Papillomaviruses (PV), it emerged, were absolutely species specific, such that human PVs could only infect humans, rabbit PV's only rabbits, and so on. They were also exquisitely tissue trophic, and the different clinical lesions were distinct diseases caused by infection with specific groups of HPV types. It became clear that within a species the individual viruses showed a predilection for either skin or internal squamous mucosae, and that within the groups of skin or mucosal viruses they could be separated into high- or low-risk types, depending upon their oncogenic potential. This was shown dramatically in the genital tract. Genital warts were shown to be associated predominantly with HPV-6 and -11 (low-risk human papillomavirus (LR-HPV)) – viruses that were almost never detected in carcinomas, whereas HPV-16, -18, and their close relatives (high-risk human papillomavirus (HR-HPV)) were associated with intraepithelial lesions, particularly in the cervix, and were detected in more than 99 percent of cervical cancers. This association with premalignant and malignant disease in humans dramatically broadened the spectrum of HPV pathogenicity, revealing these viruses

to be not just the cause of cosmetic nuisances but also important human pathogens causing life-threatening diseases.

CLASSIFICATION

The papillomaviruses are widespread in nature, infecting a wide range of species (Stanley et al. 1997). Those viruses infecting ungulates are a distinctive group in that they induce fibropapillomas with a distinctive fibroproliferative component in addition to the epithelial wart. The best studied of this group is bovine papillomavirus type 1 (BPV-1), a virus that can infect rodent cells in vitro and induce morphologic transformation, providing a biological assay with which to analyze those viral functions necessary for the induction of cell proliferation. Papillomaviruses are classified according to the species of origin and the degree of relatedness of the viral genomes according to their sequence homology. The virus types are therefore genotypes, not serotypes. PVs have been divided into five clades or supergroups, designated A–E (Chan et al. 1995) (Figure 1). The association of specific HPV types and human cancers has focused attention very much on the human viruses. Initially HPV types were distinguished from each other on the basis of molecular hybridization in liquid medium: 50 percent or less homology with a known HPV type defined a new virus type. At the 1995 meeting of the International Papillomavirus Workshop it was agreed that classification be based on the *L1* gene, and that to be classified as a new type there should be 10 percent or more sequence dissimilarity in *L1* compared to all known types. To date, more than 80 HPV types have been fully sequenced, and in addition many more partially characterized types, based on

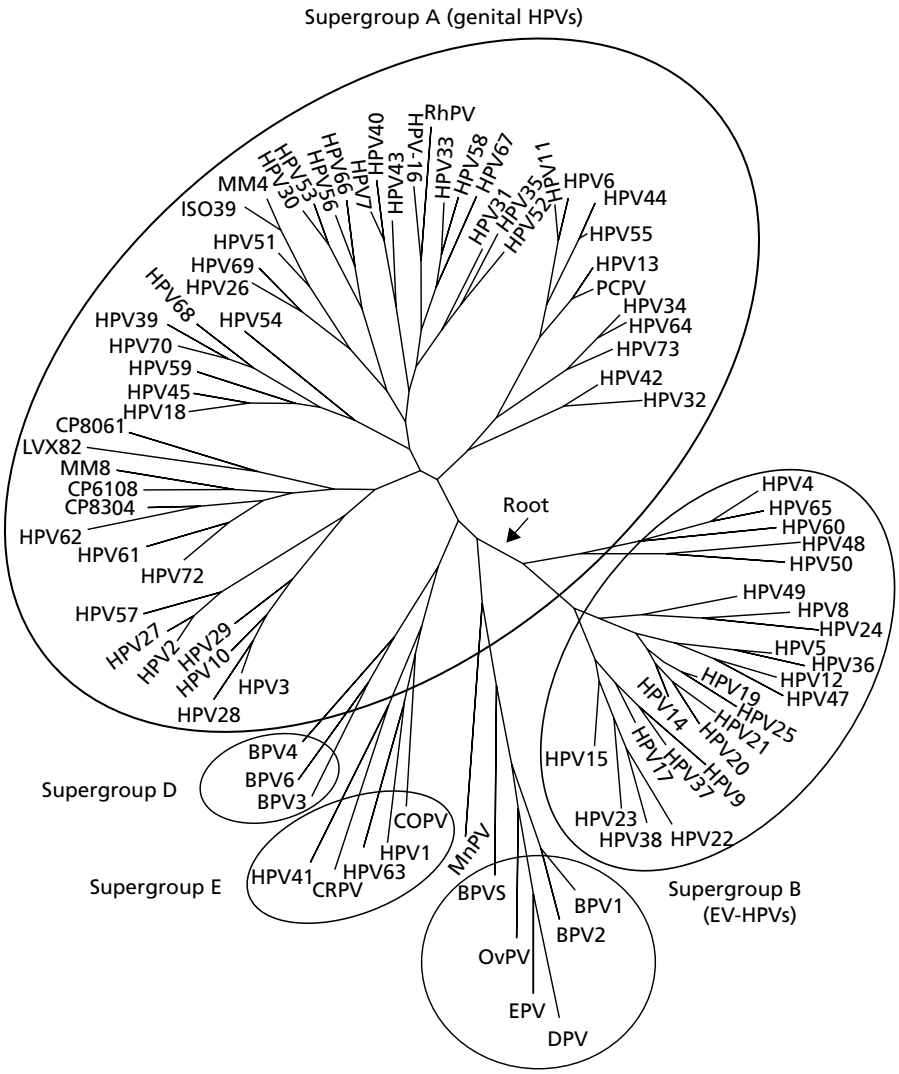

Figure 1 *Phylogenetic tree of animal and human papillomaviruses. The classification is based on nucleotide sequence comparisons using a 291-bp segment of L1. Redrawn from Chan et al. 1995, with permission.*

the *L1* open reading frame (ORF) only, have been identified (see the 'HPV sequence database' at www.stdgen.lanl.gov/stdgen/virus/hpv). Phylogenetic relationships between HPV types based on genome sequence variation indicate how these viruses have evolved and their relationship to each other. Interestingly, the clinical distinctions between skin and mucosal warts and benign and malignant lesions correlate with the virus phylogenetic tree.

BIOLOGY OF PAPILLOMAVIRUSES

Viral structure

PV particles are approximately 55 nm in diameter, harboring a single molecule of circular dsDNA of approximately 7.9 kb contained within a spherical icosahedral capsid composed of 72 pentameric capsomeres arranged on a T = 7 surface lattice. The capsomeres exist in two states, one capable of making contact with five neighbors in the 12 pentavalent capsomers, and the other capable of making contact with six neighbors in the 60 hexavalent capsomers (Baker et al. 1991) (Figure 2). The capsid is composed of the two structural proteins, the major capsid protein L1 and the minor L2. L1 is about 55 kDa in size and represents about 80 percent of the total viral protein. Expression of L1, either alone or with L2 via mammalian expression systems, results in the formation of virus-like particles (VLP) (Figure 2) that are morphologically identical to intact virus particles (Zhou et al. 1991; Kirnbauer et al. 1992; Rose et al. 1993). L1 VLPs are highly immunogenic, generating serum neutralizing antibodies (Christensen et al. 1994), and it is thought that the major neutralizing epitope is within L1. L2 is about 70 kDa, and although not essential for assembly its presence increases the efficiency of VLP production and stability of the VLPs (Hagensee et al. 1993; Kirnbauer et al. 1993; Zhou et al. 1993).

Genome organization of the papillomaviruses

The papillomaviruses exhibit a high degree of conservation of genomic organization (Figure 3). The genome can be divided into three domains: a noncoding upstream regulatory region (URR) (also known as the 'long control region'), an 'early' region comprising the ORF E6, E7, E1, E2, E4, and E5 that encode proteins required for regulation of viral DNA replication and viral gene expression, and a 'late' region encoding the L1 and L2 viral capsid proteins. The prefix 'E' or 'L' relates to the position of the ORFs within the genome, and also the timing of expression relative to vegetative viral replication. Only one strand of the dsDNA serves as the template for viral gene expression, coding for a number of polycistronic mRNA transcripts. Transcription is regulated by enhancer sequences located in the URR, which are bound by a number of cellular factors as well as the viral E2 product. The transcription start sites of viral promoters differ depending on the virus type, but in all types promoter usage is differentiation dependent. Figure 4 gives a detailed outline of the genomic organization and transcription map of HPV-16.

THE INFECTIOUS CYCLE

The virus lifecycle is the key to understanding the pathogenesis of papillomavirus-associated disease. These viruses have an absolutely restricted host range and tissue specificity; in the natural infection papillomaviruses, with the exception of the supergroup C viruses, only infect human keratinocytes or cells with the potential for squamous maturation, such as the reserve cells of the uterine cervix. There is no tissue culture system that supports a complete infectious cycle, i.e. infection of cells in culture with virus and the subsequent generation and release of new infectious virus particles. It is unlikely that the cellular receptor for the virus defines the epithelial tropism, as virions and VLPs will bind to and enter mouse fibroblasts. The nature of the receptor(s) is unclear. The evidence that the α6β4 integrin is the primary receptor (Evander et al. 1997) has not been supported in all studies (Sibbet et al. 2000), and although there is good evidence that papillomaviruses can bind heparin and cell surface glycoproteins (Joyce et al. 1999) on keratinocytes, such binding is characteristic of many viruses.

The complete infectious cycle is absolutely dependent upon the differentiation program of the keratinocyte. Virus infects keratinocytes in the basal layer of the epithelium, but only in terminally differentiated keratinocytes are viral capsid proteins and virus particles

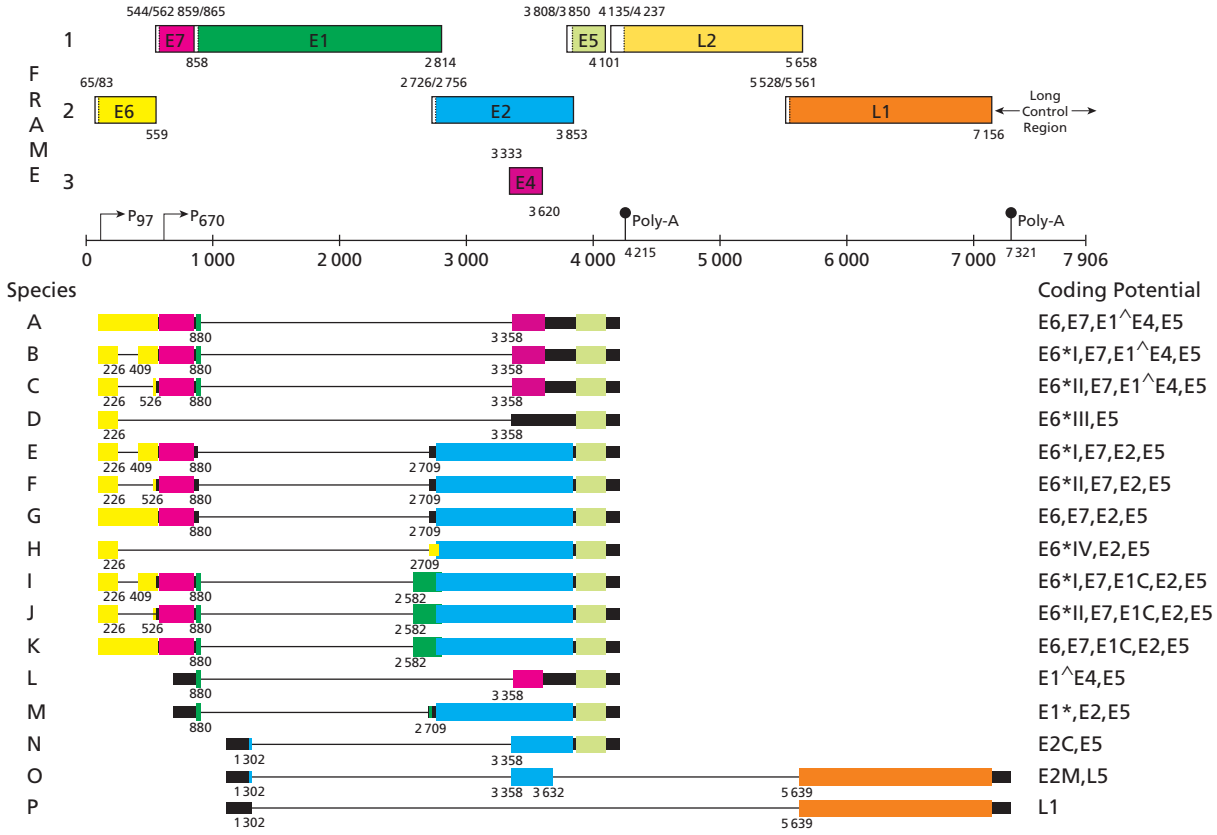

Figure 4 *Genomic organization and transcription map of HPV-16. Organization of the linearized HPV-16 genome is presented, illustrating ORFs of functional significance, well-characterized promoters (P97 and P670) and poly(A) signals. The lower panel illustrates previously characterized polycistronic mRNA species coded by the virus. These have been isolated from transfected cells and a variety of tumor cell lines and lesions. Thin black lines and colored bars represent introns and exons, respectively, and the coding potential of each species is indicated to the right. The P97 promoter is active in monolayer culture as well as systems permitting keratinocyte differentiation, and hence is the best characterized.*

assembled (Figure 5). Squamous epithelia are usually composed of 20–30 layers of cells exhibiting a coordinated pattern of gene expression concurrent with differentiation. It is thought that HPV infections occur via microwounds, which expose basal cells to viral entry. Despite the lack of unequivocal evidence, the current hypothesis is that the specific target cell for infection is the keratinocyte stem cell that resides within the hair follicle and the basal layer of squamous epithelium (Stanley 2001a). Following infection, viral genomes are established as stable episomes within the host nucleus by amplifying to approximately 20–100 copies per cell: these subsequently replicate coordinately with cellular DNA replication in a phase of plasmid maintenance.

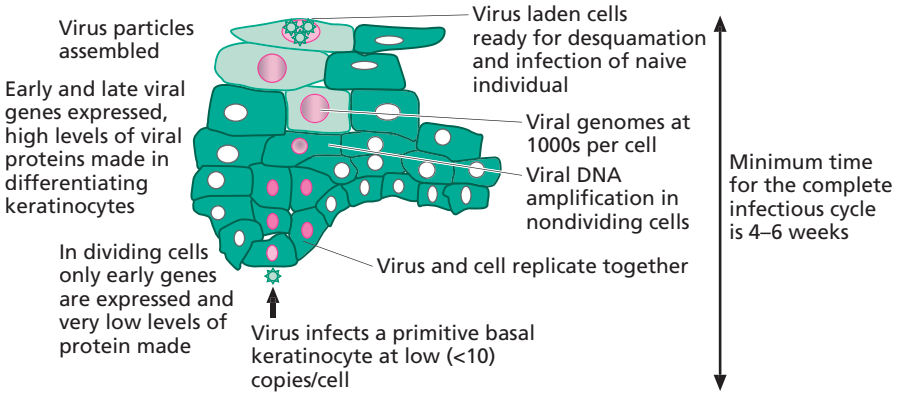

Figure 5 *The* Papillomavirus *infectious cycle*

As infected cells migrate up from the basal region and undergo differentiation, cellular replication ceases and, coordinate with the expression of differentiation-specific markers such as filaggrin, activation of differentiation-dependent late gene expression and viral capsid assembly occurs, along with amplification of viral DNA to thousands of copies per cell (Stanley 1994; Stanley et al. 1989). Koilocytes, the pathognomonic cells of papillomavirus infections, are the location of viral DNA amplification, late gene expression, and viral assembly. Productive infection only slightly alters the normal differentiation programme, with the most significant change being the retention of nuclei throughout all layers.

Our knowledge of the temporal and spatial patterns of viral gene expression comes mainly from animal models such as the dog, cow, and rabbit, and the rodent xenograft system first described by Kreider and colleagues (Kreider et al. 1987), which is permissive for vegetative growth of some HPVs. These studies show that in the first 3–4 weeks after infection with large amounts of virus, viral DNA cannot be detected in the epithelium by in situ hybridization (Stoler et al. 1990; Nicholls et al. 1999). At 4–5 weeks viral DNA can be detected in the lower layers of the epithelium and transcripts for the early genes are present. At 5–8 weeks strong signals for viral DNA are detected in the middle to upper layers of the epithelium, and in some cells viral copy number can be of the order of 1 000 or more per cell. E6 and E7 mRNAs are present at low levels in the lower dividing epithelial layers but are highly abundant in the upper differentiating layers. At about 8 weeks post-infection L1 and L2 capsid protein expression can be detected in the most superficial cells of the epithelium. The sequence of events for one of these experimental models, the canine oral papillomavirus (COPV), a low-risk mucosal virus infecting the oropharynx of dogs, is shown in Figure 6. There are variations in this spatial and temporal expression pattern and these have recently been elegantly outlined (Peh et al. 2002). Importantly, the high-risk genital HPVs (16, 18, etc.) show a similar spatial and temporal pattern of gene expression, but the regulation of the early genes *E6* and *E7* is under very tight control in the proliferating compartment of the epithelium, with very low levels of mRNA expression in these cells. E6 and E7 mRNAs are expressed abundantly only in the upper stratum spinosum and granulosum (Durst et al. 1992; Higgins et al. 1992).

TARGET CELL FOR INFECTION AND VIRAL LATENCY

The dependence upon the keratinocyte lineage for viral gene expression extends to the target cell for infection. In experimental CRPV infections, viral gene transcription is detected first in the hair follicle, in cells that have the characteristics of stem cells (Schmitt et al. 1996) This is also true in COPV, where viral DNA amplification and early gene transcription are first detected at the extreme tips of the rete ridges, thought to be the site of interfollicular keratinocyte stem cells (Figure 6). If the target cell for infection is the stem cell then this does offer an explanation for some interesting aspects of papillomavirus biology. There is, for example, the phenomenon of the lag phase between infection and the first detection of viral DNA and early gene expression. The length of this lag in experimental models such as the rabbit, the dog, and rodent xenografts of HPV 11, is consistently between 3 and 5 weeks. Anecdotal evidence in humans suggests a similar time lag for genital warts (Oriel 1971). One attractive explanation for this is that the virus infects a stem cell in the G_0 phase of the cell cycle. The 3–5-week delay before viral gene expression is detectable would then reflect the time for the stem cell to enter G_1, divide, and for committed daughter cells to enter the transit amplifying population of basal and parabasal cells permissive for viral gene expression.

Dependence upon the stem cell milieu for infection and immediate early viral gene expression would also partly explain the phenomenon of latency. HPV is frequently present as a latent infection in the female genital tract (Toon et al. 1986), and the frequent lesion recurrence observed in respiratory papillomatosis is generally believed to reflect reactivation of latent infection, rather than reinfection (Abramson et al. 1987). This is supported by the observation that histologically normal, but HPV positive, laryngeal tissues express low-abundance transcripts coding for E1 and E2 (Maran et al. 1995). Similarly, in the rabbit, low doses of CRPV lead to viral persistence and expression of truncated E1 and E2 transcripts, but no lesion unless – and until – reactivation is induced by skin irritation (Amella et al. 1994). Furthermore, CRPV can persist at the site of regressed papillomas in 60 percent of cases (Selvakumar et al. 1997) with occasional lesion recurrence, and similar phenomena are seen in BPV (Campo et al. 1994) and COPV infections (Moore et al. 2002). Latency is a poorly understood aspect of papillomavirus biology but clearly of importance for therapeutic and prophylactic intervention strategies.

REGULATION OF GENE EXPRESSION

Papillomavirus transcription is complex owing to the presence of multiple promoters and the differential production of mRNA species in different cells; viral gene expression is regulated both temporally and spatially. Transcription has been most extensively analysed for BPV-1 (Baker 1993), but information is available for the high-risk genital HPVs (Doorbar et al.

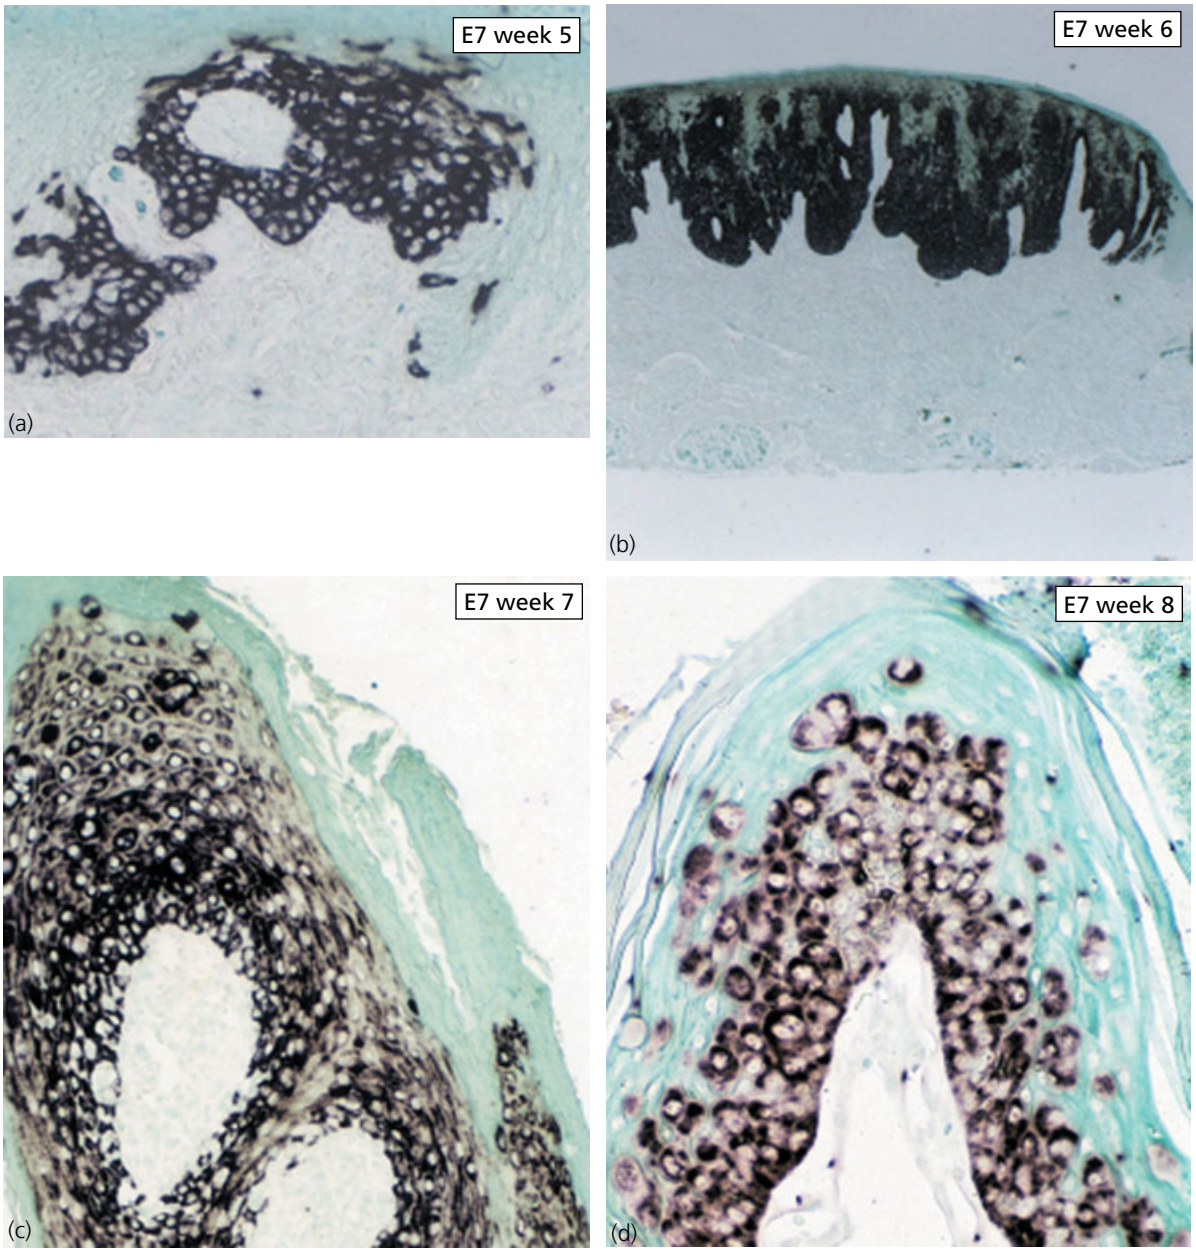

Figure 6 *Temporal and spatial expression of* Papillomavirus *genes in canine oral papillomavirus infection.* **(a–d)** *In situ RNA hybridization of experimental COPV lesions with digoxigenin-labeled E7 probe. Abundant transcripts in detected in early lesions. At week 6 there are abundant basal layer and some suprabasal transcripts persisting through to week 8. (Continued over)*

1990; Stubenrauch and Laimins 1999) and the following discussion concentrates on these.

Early gene expression

Early gene expression of genital HPVs is positively and negatively modulated by a complex interplay between a variety of cellular transcription factors and the viral E2 protein. Early polycistronic transcripts of the HR-HPVs are initiated at the early promoter upstream of the E6 ORF and terminate at a polyadenylation site at the end of the early region (Figure 3). The promoter, known as P97 in HPV-16 and HPV-31, and P105 in HPV-18 by virtue of the nucleotide from which transcription is initiated, comprises binding sites (Desaintes and Demeret 1996) for a number of cellular factors that are essential for viral transcription (see Figure 4). Binding sites for the viral E2 protein are also located within the early promoter. These allow E2 to exert its function as a transcriptional regulator.

Early gene transcription is further regulated by a *cis*-acting transcriptional enhancer located in the central

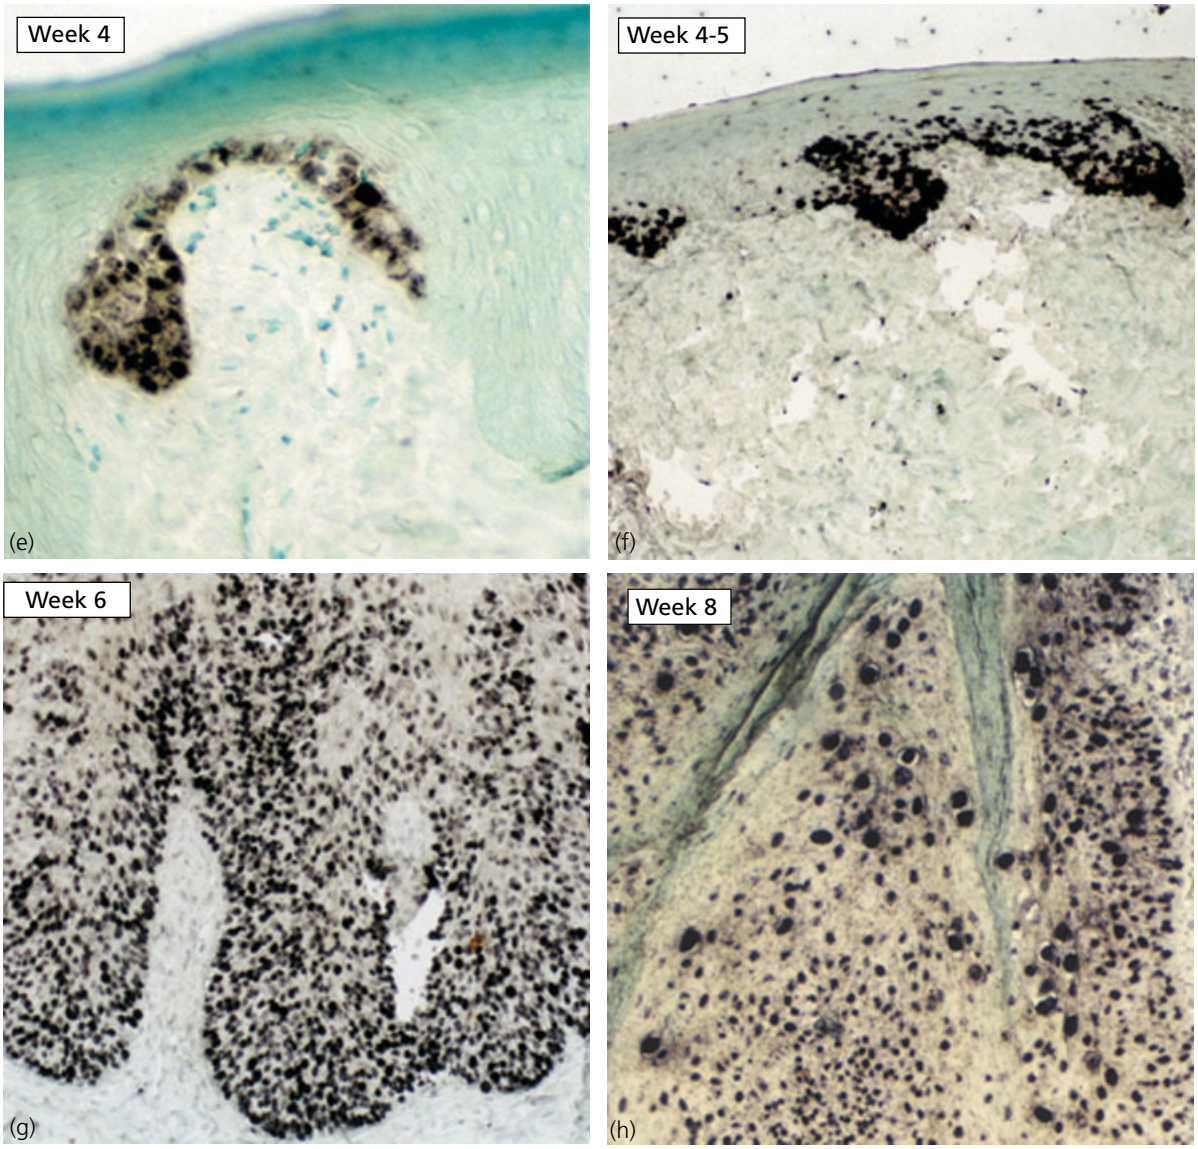

Figure 6 *Temporal and spatial expression of* Papillomavirus *genes in canine oral papillomavirus infection. (Continued)* **(e–h)** *In situ DNA hybridization of experimental COPV lesions with a digoxigenin-labeled genomic COPV probe. Viral DNA was undetectable from weeks 1 to 3 post infection. By week 4, viral DNA was found in multiple clusters each arising from a rete ridge. By 6 weeks almost all basal cells and a majority of suprabasal cells were positive for viral DNA. At week 8 sporadic cells in the more superficial epithelium had the strongest signal, together with vacuolated cytoplasm typical of koilocytes. (Continued over)*

region of the URR. This is a major determinant of HPV epithelial tropism, as it is only active in epithelial cells. The epithelial specificity of action appears to be conferred not through the action of keratinocyte-specific activators, but rather through the combinatorial action of multiple ubiquitous cellular transcription factors (Desaintes and Demeret 1996). Although the binding elements for these factors, as well as their spatial organization, vary according to viral type, organization of the enhancer appears quite conserved among the genital HPVs (O'Connor et al. 1995). In the case of the HPV-16 enhancer (see Figure 7), identified binding sites that have also been shown to regulate a number of other genital HPVs include those for NF1 (Apt et al. 1993), AP-1 (Chan et al. 1990), Oct-1 (O'Connor and Bernard 1995; Sibbet and Campo 1990), TEF-1 (Ishiji et al. 1992), and YY1 (O'Connor et al. 1996). Activity of the early promoter is differentiation dependent, with extremely low levels of early transcripts being detected in basal cells of infected epithelium, and expression increasing in the intermediate layers (Durst et al. 1992; Higgins et al. 1992; Stoler et al. 1992; Cheng et al. 1995).

There is an important difference in the expression of the E6 and E7 mRNAs of the HR-HPVs and the LR-HPVs. The HR-HPVs are expressed from a single

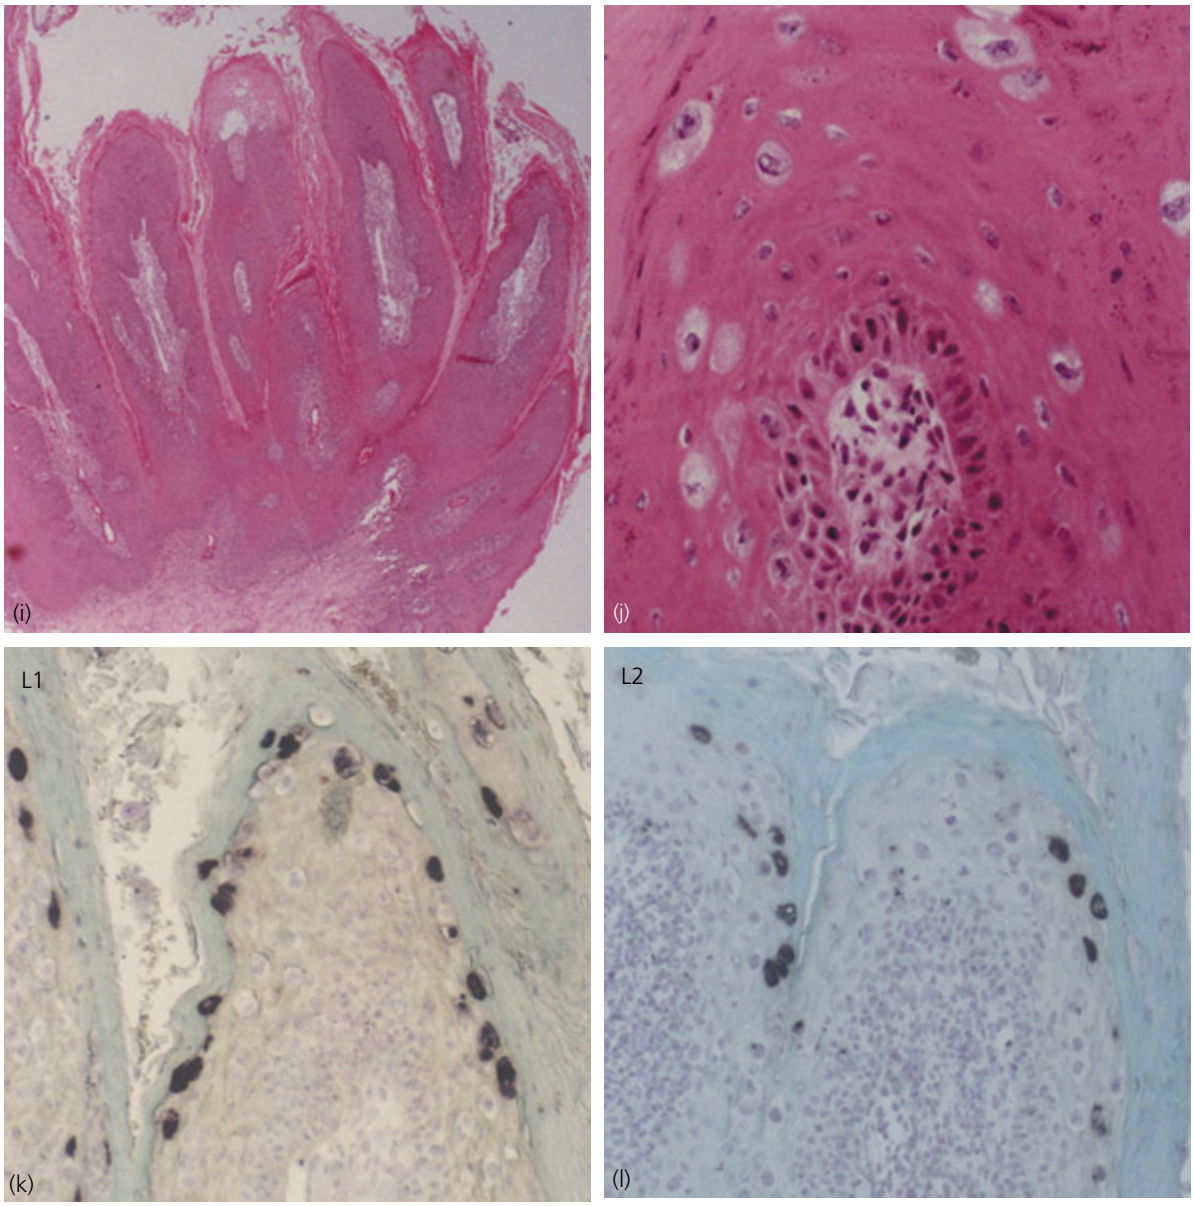

Figure 6 *Temporal and spatial expression of* Papillomavirus *genes in canine oral papillomavirus infection. promoter that directs the expression of mRNAs for E6 and E7 with splices in the *E6* gene. The mRNAs with spliced E6 splice to the 5′ end of the E6 ORF (E6*) to a transition frame with a stop codon allowing sufficient spacing for translation reinitiation of the E7 ORF. In contrast, the *E6* and *E7* of the LR-HPVs are expressed from two independent promoters (Chow and Broker 1997).

Late gene expression

The application of in vitro systems, such as organotypic raft cultures (Asselineau et al. 1986), that induce stratification and terminal differentiation of keratinocytes has permitted analysis of late gene expression (Wilson et al. 1992). The raft culture system can fully support the late stages of the virus lifecycle (Bedell et al. 1991; Stanley 1994). In genital HPVs a differentiation-dependent promoter has been detected that has a transcription start site within the E7 ORF (see Figure 4) (Grassmann et al. 1996; Hummel et al. 1992). Most polycistronic late transcripts initiated from this promoter have coding potential for the E1–E4 fusion protein (Hummel et al. 1995). More recently, it has been shown that transcripts encoding E1 and E2 are also generated from the late

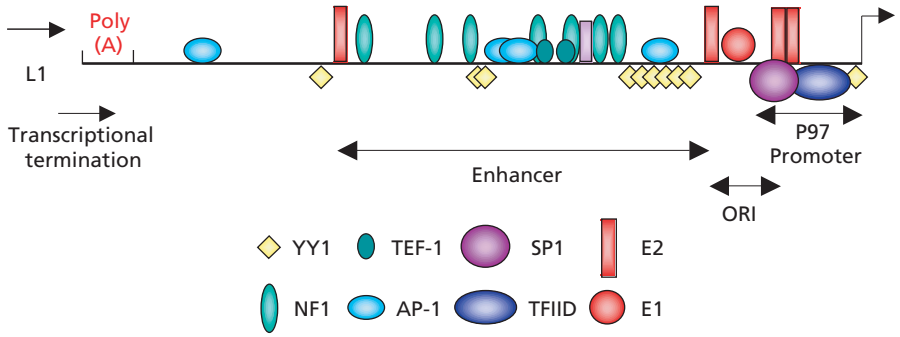

Figure 7 *Schematic representation of the HPV-16 URR (O'Connor et al., 1996). The E2 binding sites divide the URR into three functional distinct regions referred to as the 5′, central, and 3′ segments. The 5′ segment of the URR contains a transcription termination signal (poly(A)), the central segment contains the epithelial cell-specific enhancer comprising the majority of the transcription factor binding sites, and the 3′ segment contains the origin of replication (ORI), the E1 binding site, and the P97 promoter. Shown are the binding sites for a number of transcription factors with a role in transcriptional control of all genital HPVs.*

promoter (Klumpp and Laimins 1999). Also generated are transcripts coding for the L1 and L2 capsid proteins, which are translated from mRNAs that utilize the late polyadenylation signal located within the URR (Terhune et al. 1999). Importantly, the organotypic culture systems show clearly that the induction of late gene expression requires that the viral genomes be maintained as extrachromosomal elements, and that the induction of terminal differentiation alone is insufficient (Frattini et al. 1996).

REGULATION OF HPV REPLICATION

Viral replication is dependent on the action of viral proteins and components of the cellular replication machinery, including DNA polymerase α-primase, DNA polymerase δ, replication protein A (RPA), replication protein C (RPC), proliferating cell nuclear antigen (PCNA), and topoisomerases I and II (Desaintes and Demeret 1996). These are not present normally in differentiating cells and are induced as a consequence of the viral E7 protein. In transient replication assays (Chiang et al. 1992; Del Vecchio et al. 1992; Ustav et al. 1991) and in cell-free systems (Kuo et al. 1994) the viral proteins E1 and E2 are required for efficient replication of viral origin of replication (ORI)-containing plasmids. However, in certain transient replication studies low-level replication of ORI-containing plasmids has been observed if E1 alone is expressed (Gopalakrishnan and Khan 1994; Sakai et al. 1996), indicating that E2 has an auxiliary function in viral replication and that E1 is the principal replication protein. E2 is considered a specificity factor, directing the replication initiator E1 preferentially to viral DNA to initiate highly efficient virus-specific replication. However, E2 mediates interaction of PV genomes with host chromosomes, suggesting that during plasmid maintenance E2 ensures that viral genomes are segregated to daughter cells in approximately equal numbers (Skiadopoulos and McBride 1998).

PROPERTIES AND FUNCTIONS OF VIRAL ORFS

Many biochemical properties and functions of PV ORFs were originally elucidated using BPV-1 as a model system. Many of these functions have proved applicable to HPVs.

E1 ORF

The product of the E1 ORF is a 600–650 amino acid nuclear phosphoprotein with structural and sequence similarities to regions of the simian virus 40 (SV40) large T antigen required for viral replication initiation. Consistent with a replication initiator role for the E1 protein, it binds the viral origin ORI and exhibits ATPase and ATP-dependent helicase activities (Desaintes and Demeret 1996). Hence, together with the product of the E2 ORF, expression of *E1* is critical for efficient viral DNA replication and thus plays an essential role in maintenance of episomal viral genomes during the HPV lifecycle. *E1* is the most conserved of all the PV genes, and hence *E1* gene products of different PVs are expected to be comparable in terms of both structure and function.

E1 forms complexes with E2 in solution (Blitz and Laimins 1991; Frattini and Laimins 1994; Mohr et al. 1990). Although E1 alone can bind with low affinity to the A/T-rich sequence in the viral ORI (Frattini and Laimins 1994), E1:E2 complexes bind the ORI with higher affinity and specificity (Kuo et al. 1994), which is attributable to the presence of E2-binding sites flanking the single E1-binding site in the viral ORI (see Figure 2). E2 acts as a specificity factor to promote highly efficient virus-specific replication. In the current model, the E1:E2:ORI complex constitutes the inactive preinitiation complex. This serves as a precursor for the recruitment of additional E1 molecules and the formation of a multimeric E1 complex bound to the ORI

(Lusky et al. 1994). In vitro, this is accompanied by displacement of E2 from the origin (Lusky et al. 1994). E1 assembles into hexameric structures, with hexamer formation concomitant with ATPase activity and DNA unwinding (Sedman and Stenlund 1998). Thus, the hexameric form of E1 is the enzymatically active ATP-dependent helicase required during the elongation phase of replication to unwind DNA ahead of the replication fork (Hughes and Romanos 1993).

E1 also interacts with host replication factors that are required for viral replication. For example, it interacts with DNA polymerase α-primase and brings it to the viral ORI in order to initiate replication (Masterson et al. 1998). Thus the combination of the multimeric E1:ORI complex and recruited cellular factors constitutes the active replication 'initiation' complex.

E2 ORF

The product of the E2 ORF is a regulator of both viral transcription and replication. E2 is a nuclear phosphoprotein comprising an N-terminal transactivation domain and a C-terminal DNA-binding domain, both highly conserved among all PVs, separated by a nonconserved 'hinge' region of variable length. E2 binds to DNA as a dimer, with α-helices from each monomer forming specific contacts with DNA. The consensus E2-binding site is the palindromic sequence ACCGNNNCGGT, of which there are four in the viral URR of genital HPVs (see Figure 7). The role of E2, together with E1, in viral replication has been discussed above.

Most experiments have demonstrated that, unlike BPV-1 E2, the E2 proteins of mucosal HPVs act as transcriptional repressors of the early viral promoter (Bernard et al. 1989). Repression depends on the interaction between E2 and its promoter proximal binding sites at the transcriptional control region, and this is proposed to hinder assembly of the transcription initiation complex (Dong et al. 1994). However, it has also been demonstrated that E2 can *trans*-activate gene expression from the early promoter when specific E2-binding sites are mutated (Thierry and Howley 1991) One model suggests that at low concentration E2 binds the high-affinity promoter distal E2-binding site and *trans*-activates the early promoter, whereas at higher concentrations the promoter proximal sites are bound and transcription is repressed (Steger and Corbach 1997). The E2 of both high- and low-risk genital HPVs can also influence transcription of host genes, and can downregulate the promoter of the reverse transcriptase component of telomerase (Lee et al. 2002).

E4 ORF

The most abundant mRNA species detected in productive HPV infection initiates from the late promoter, splices a short 5′ sequence of the E1 ORF to the E4 ORF, and codes for the major product of the E4 ORF, the E1–E4 fusion protein (referred to hereafter as E4) (Desaintes and Demeret 1996). E4 proteins of cutaneous and mucosal HPVs vary greatly in terms of sequence homology and biological properties. The E4 of the mucosal PVs is a cytoplasmic phosphoprotein of around 90 amino acids that can self-associate to form multimeric species (Bryan et al. 1998). It comprises relatively conserved N-terminal and C-terminal regions, separated by a highly variable region. Although E4 is located in the early gene region, transcripts with coding potential for E4 are expressed at a high level late in the productive lifecycle through activation of the differentiation-dependent late promoter located in the E7 ORF. The function of E4 is poorly understood, but current hypotheses suggest that it may function at the level of control of viral replication and/or release of infectious virions.

In cultured human keratinocytes E4 has been shown to associate with the keratin intermediate filament (IF) network and, in the case of HPV-16, to cause its collapse (Doorbar et al. 1991; Roberts et al. 1993). A leucine-rich N-terminal motif was a crucial determinant in mediating cytoplasmic localization of E4, whereas C-terminal residues mediated self-association, association with the keratin IF network, and efficient disruption of the keratin IF network (Bryan et al. 1998; Roberts et al. 1997). Because of the observed cytopathic effect, it has been hypothesized that E4 may enhance the release of infectious virions in superficial layers by promoting cell lysis (Doorbar et al. 1991). However, although colocalization of E4 with the keratin IF network was demonstrated within HPV-infected epithelium, collapse of the network was not (Sterling et al. 1993; Pray and Laimins 1995). More recently, it has been shown that E4 binds and disrupts specific components of the cornified cell envelope (CCE), contributing to its altered physical characteristics of HPV-11-infected epithelium (Brown and Bryan 2000; Bryan and Brown 2000). Given that one of these is increased cell fragility, the hypothesis that E4 may enhance virion release may hold true, via disruption of the CCE and/or collapse of the keratin IF network.

Expression of HPV-16 *E4* in SiHa cells results in arrest of the cell cycle at G2 and colocalization of the Cdc2/cyclin B mitosis-promoting complex with E4 at the keratin IF network (Davy et al. 2002). Because nuclear localization of this complex is required for entry into mitosis, cytoplasmic sequestration would account for the observed G2 arrest. Thus, it has been suggested that E4-induced G2 arrest, combined with the viral oncogene cell cycle progression out of G_1 phase, creates a 'pseudo S-phase' environment ideal for replication of the viral genome.

E5 ORF

The contribution of the E5 protein to the HPV lifecycle is poorly understood. However, given that it is among

the most abundant transcripts in low-grade intraepithelial lesions, its cellular effects are likely to be important in productive HPV infections. HPV-16 E5 is a small hydrophobic protein of approximately 90 amino acids in length. Apart from its overall hydrophobic sequence, it does not share significant sequence homology with BPV-1 E5 (DiMaio and Mattoon 2001). Like BPV-1 E5, HPV-16 E5 localizes to the Golgi apparatus, endoplasmic reticulum, and nuclear membranes (Conrad et al. 1993), but unlike its bovine counterpart has only weak transforming activity (DiMaio and Mattoon 2001). The transforming capacity of HPV16 E5 correlates with its ability to inhibit downregulation of the EGF receptor in human keratinocytes (Straight et al. 1993). This is consistent with the enhanced transforming capacity of E5 in the presence of EGF (Bouvard et al. 1994). It has been shown that E5 interacts with the 16 kDa component of the vacuolar proton ATPase (Conrad et al. 1993). This impairs its function in acidification of endosomes, which is essential for their proteolytic functions (Conrad et al. 1993; Straight et al. 1995). Hence, the current model is that HR-HPV E5 transforms cells by increasing their sensitivity to extracellular EGF levels by increasing receptor recycling to the membrane (DiMaio and Mattoon 2001).

E6 ORF

The viral oncoproteins E6 and E7 are the major transforming and immortalizing proteins of the oncogenic or HR-HPVs. The transforming and immortalizing capacity of the oncoproteins of specific HPV types correlates with viral oncogenicity in vivo. Thus, the association of HR-HPVs, but not LR-HPVs, with the development of cervical carcinoma is attributable to differences in the activity of the E6 and E7 proteins. However, the properties of these proteins must be viewed primarily in terms of their function in the virus lifecycle, as it is in this context that they have evolved.

STRUCTURE AND LOCALIZATION OF E6

The HPV E6 protein is a polypeptide of approximately 150 amino acids. Although there is sequence variation of E6 in different HPV types, all retain strict conservation of four C–X–X–C motifs that allow the formation of two zinc fingers (Barbosa et al. 1989; Grossman and Laimins 1989). Owing to low levels of endogenous E6, detection of its intracellular location has been difficult. However, induction of high-level E6 expression with a baculovirus vector reveals localization to the nucleus, and also to nonnuclear membranes (Grossman et al. 1989), consistent with the notion that E6 protein is multifunctional.

INTERACTION BETWEEN E6 AND P53

A large number of cellular targets of HR-HPV E6 have been defined, although the best studied is the interaction with the tumor suppressor gene (TSG) *TP53*. The E6 protein of HR-HPVs has been shown to bind in vitro translated p53 (Werness et al. 1990), resulting in degradation of the p53 via the ATP-dependent ubiquitin pathway (Scheffner et al. 1990). This is consistent with the observation that low levels of wildtype p53 are detected in HR-HPV-positive cervical cancer cell lines and E6-immortalized human mammary epithelial cells (Band et al. 1991; Hubbert et al. 1992; Scheffner et al. 1991). There are conflicting reports as to whether E6 of LR-HPV can bind p53 (Crook et al. 1991; Lechner and Laimins 1994; Werness et al. 1990). However, this is a low-affinity interaction compared to that of HR-HPV E6, and does not induce degradation of p53. Thus, the oncogenicity of HPVs correlates with an ability to bind and induce the degradation of p53. Indeed, the demonstration that HR-HPV E6-expressing cells do not generally undergo cell cycle arrest in response to DNA damage shows that the HR-HPV E6/TP53 interaction can abrogate the normal function of this TSG (Kessis et al. 1993).

The induction of degradation of p53 by E6 is mediated by a cellular protein E6-associated protein (E6-AP) which can bind E6 of HR-HPVs, but not the E6 of LR-HPVs, in the absence of p53 (Huibregtse et al. 1991; Scheffner et al. 1993). E6 recruits E6-AP to prevent the accumulation of p53.

ADDITIONAL CELLULAR TARGETS OF E6

E6 has binding partners apart from p53 (zur Hausen 2000) (Table 1). The consequences of these various protein/protein-binding reactions with regard to E6 oncogenicity are not currently understood, but they do involve key aspects of cellular function and behavior in the maintenance of tissue architecture, the disruption of which accompanies carcinogenic progression. However, given the low levels of E6 expressed in HPV-positive lesions, it is uncertain which interactions take place in an infected cell during permissive viral growth.

FUNCTION OF E6 IN THE VIRUS LIFE CYCLE

Viral DNA amplification occurs in terminally differentiated postmitotic cells and, because the virus requires the host DNA replication machinery to achieve this, a central role of the E7 protein is to induce S-phase entry. However, one response of a normal cell to the induction of inappropriate DNA replication – for example during differentiation, at confluence, or upon growth factor withdrawal – is growth arrest or apoptosis via induction of p53. Indeed, E7-expressing primary keratinocytes show an increase in p53 levels (Demers et al. 1994). Through its ability to bind and degrade p53, the E6 protein mediates inhibition of apoptosis, a function elegantly demonstrated in transgenic mice expressing the HPV-16 oncoproteins in the ocular lens. The expression

Cellular binding protein or property	Notes	References
ERC-55	Calcium-binding protein of unknown function. The mouse homologue is the vitamin D receptor-associated factor that transduces the growth-suppressive effects of vitamin D. Thus, the association with E6 may inhibit these growth-suppressing signals	Imai et al. 1991
Paxillin	Focal adhesion protein that transduces signals from the plasma membrane to focal adhesions and the actin cytoskeleton. The association of E6 possibly disrupts growth-inhibitory signals from cell–cell contact	Turner 2000
hDLG	Membrane-associated PDZ motif containing protein that is the human homologue of *Drosophila* discs large TSG. Binds APC and negatively regulates cell-cycle progression. E6 induces proteasome-mediated degradation and could inhibit the inhibitory hDLG/APC interaction and also cell–cell contact	Gardiol et al. 1999
MCM7	Required for formation of the DNA replication licensing system, which allows initiation of cellular DNA replication and restricts it to a single round per cell cycle. The E6 association may be a normal requirement for the viral lifecycle	Kukimoto et al. 1998
Interferon regulatory factor (IRF-3)	Activated in response to virus infection to induce expression of the antiviral type I interferon (IFN) IFN-β. The E6 interaction does not cause degradation of IRF-3, but reduces expression of IFN-β. This is likely to be of significance in the normal viral lifecycle	Ronco et al. 1998
Enhanced degradation of MYC and BAC	BAK is a proapoptotic member of the BCL-2 family, expressed in differentiated epithelial cells. MYC can also induce apoptosis if proliferation is unscheduled. The E6-induced degradation of MYC and BAK may partly explain the TP53-independent inhibition of apoptosis by E6. This may also be of significance in the normal viral lifecycle	Thomas and Banks 1999
Induction of hTERT expression	Retrovirally delivered E6 can induce high levels of telomerase activity in preimmortal keratinocytes. This is mediated by activation of the hTERT promoter. The mechanism of activation is poorly understood, but as upregulation of the hTERT promoter correlates with the ability of E6 to bind E6-AP, it is possible that E6 targets a negative regulator of expression for degradation	Klingelhutz et al. 1996

of E7 alone induced cellular proliferation in spatially inappropriate regions and apoptosis of these cells before differentiation could occur. The expression of E6 alone inhibited the apoptosis that was observed in the lenses of nontransgenic embryos, whereas co-expression of E6 and E7 resulted in abrogation of the E7-induced apoptosis, and led to tumor formation in 40 percent of adult mice (Griep et al. 1993; Pan and Griep 1994). The ability of E6 to bind and degrade BAK and MYC (see Table 2) is consistent with inhibition of p53-independent apoptosis.

THE E6* PROTEIN

A number of early transcripts of high-risk, but not low-risk, HPVs utilize a splice donor site within the E6 ORF to yield coding potential for a number of nontransforming truncated E6 proteins known as E6* (Schwarz et al. 1985). It has been shown that E6* is capable of interacting with both the full-length E6 protein and E6-AP in vitro, blocking the association of E6 with TP53 (Pim et al. 1997). As a consequence, E6* proteins can inhibit the E6-induced degradation of TP53 (Pim et al. 1997; Shally et al. 1996). The role of E6* in the viral lifecycle remains unclear, however.

E7 ORF

STRUCTURE AND LOCALIZATION OF E7

The HPV E7 protein is a phosphoprotein of approximately 100 amino acids. Consistent with its multifunctional nature, E7 has been detected at a variety of locations within the cell, including the cytoplasm, nucleus, and nucleoli (Greenfield et al. 1991; Smotkin and Wettstein 1987). The N-terminal region of E7 comprises two regions known as conserved domains 1 and 2 (CD1 and CD2). CD2 contains a 'pocket protein'-binding L–X–C–X–E motif, and also a consensus phosphorylation site for casein kinase II (CK II). A third conserved region, CD3, resides at the C terminus and comprises two C–X–X–C motifs with the ability to bind zinc and form a zinc finger (Barbosa et al. 1989; McIntyre et al. 1993). This domain confers the ability of

Table 2 *Additional cellular targets of the E7 oncoprotein*

Cellular binding protein	Notes	References
$p21^{WAF1/CIP1}$ and $p27^{KIP1}$	Inhibitors of cyclin A/E-dependent kinases, with a role in cell-cycle arrest, differentiation, and apoptosis. Association with E7 abrogates these activities. Effects on terminal differentiation-associated growth arrest may possibly play a role in the viral life cycle	Funk et al. 1997
TATA box-binding protein	Component of the TFIID transcription factor complex. Interaction of E7 may control expression of genes related to E7-associated transformation	Massimi et al. 1997
JUN	Member of the AP-1 family of transcription factors. The E7 interaction can induce transcription from JUN-responsive promoters. However, JUN also binds RB and induces activation of AP-1-regulated genes in differentiated keratinocytes. The interaction of E7 with JUN inhibits this activation. Thus, E7 can act as both a positive and negative regulator of JUN-responsive promoters	Antinore et al. 1996
M2 pyruvate kinase (M2-PK)	This is the first example of a cytoplasmic, noncell cycle-associated target of E7. In its tetrameric form, M2-PK promotes flux of metabolites through the glycolytic pathway. Binding of E7 converts M2-PK to a dimeric form, which decreases this flux. This increases the pool of metabolites available for biosynthesis of nucleic acids. Thus, this interaction may play an important role in the viral lifecycle by increasing the pool of nucleic acids available for viral replication	Zwerschke et al. 1999

E7 to form homodimers, and mutational analysis has shown that it also contributes to the transforming potential of the HR-HPV E7 proteins (Edmonds and Vousden 1989; McIntyre et al. 1993).

INTERACTION OF E7 WITH RB AND OTHER POCKET PROTEINS

The best-characterized interaction of HPV E7 is with the TSG RB. A significant breakthrough regarding the molecular basis of transformation by HPV E7 was the demonstration that HPV-16 E7 can bind pRB both in vitro and in vivo (Munger et al. 1989). Furthermore, the affinity of this association is greater for HR-HPV than for LR-HPV E7 (Munger et al. 1989), suggesting that this property is likely to contribute to the oncogenic potential of HR-HPVs. Indeed, mutational analysis has demonstrated that E7-induced transformation is impaired if the pRB/E7 association is disrupted (Barbosa et al. 1990; Edmonds and Vousden 1989; Watanabe et al. 1990). E7 preferentially binds the hypophosphorylated form of pRB (Imai et al. 1991), disrupting the pRB/E2F association and thus inducing the expression of E2F-dependent genes required for G_1–S progression (Chellappan et al. 1992). It has also been shown that HR-HPV E7 induces degradation of pRB via the ubiquitin-mediated proteasomal pathway (Boyer et al. 1996). Thus, efficient abrogation of pRB function by E7 is mediated by protein degradation as well as binding and, consistent with this, the transforming capacity of E7 mutants correlates more closely with their ability to degrade pRB rather than just bind it (Jones and Munger 1996).

E7 also binds the pRB-related pocket proteins p107 and p130 (Dyson et al. 1992), which are also involved in cell-cycle regulation via association with E2F proteins. However, given that similar sequences of E7 are required to mediate interactions with all the pocket proteins, it is difficult to determine which of these are the most functionally significant targets of E7 using mutational analysis.

ADDITIONAL CELLULAR TARGETS OF E7

Mutational studies have shown that the E7/pRB interaction is necessary, but not sufficient, for cellular transformation (Edmonds and Vousden 1989; Phelps et al. 1992). Consistent with this, a number of additional cellular targets of E7 are now recognized (Table 2). These are likely to contribute to the ability of E7 to modulate the cell cycle as well as other cellular activities. As with E6, a number of these targets are more efficiently abrogated by E7 from HR-HPVs, and thus may further contribute to the oncogenic potential of HR-HPVs. However, the low level of E7 protein detected in clinical lesions raises the issue of which of these interactions are relevant in permissive infection.

FUNCTION OF E7 IN THE VIRUS LIFECYCLE

Because they do not encode a unique DNA polymerase, papillomaviruses are completely dependent upon the host DNA replication machinery for generation of progeny virions. Given that viral vegetative DNA replication occurs in postmitotic differentiated cells, this presents a problem for the virus. In a usual differentiation program, as postmitotic differentiated cells migrate

up the epithelium their nuclei are gradually degraded and no longer active. Thus, an important role of the virus is to maintain suprabasal cells in a replication-competent state and reactivate the host DNA replication machinery while preserving the differentiation process to allow late gene expression.

It has been shown that the E7 of HR-HPVs and, to a lesser extent, LR-HPVs under the control of the homologous URR, is sufficient to induce expression of proliferating cell nuclear antigen (PCNA) and induce cellular DNA synthesis within suprabasal cells (Cheng et al. 1995). Thus, induction of entry into S-phase and the activation of host DNA replication machinery is a crucial role of the E7 protein. Unscheduled exit from G_1 can lead to apoptosis, and this is overcome by the viral oncoprotein E6. The cellular targets of E7 are consistent with this function. Through its interaction with members of the RB family of pocket proteins, E7 can induce the activity of the E2F family of transcription factors that control the expression of genes required for entry into S-phase.

Abrogation of the effects of cyclin-dependent kinase inhibitors (CDKI) such as $p21^{WAF1/CIP1}$ and $p27^{KIP1}$ is another important role of E7 in the viral lifecycle. CDKIs have roles both in cell-cycle regulation and in keratinocyte differentiation (Missero et al. 1995; Di Cunto et al. 1998) In vitro studies have shown that E7 inhibits the cell-cycle arrest function of both $p21^{WAF1/CIP1}$ and $p27^{KIP1}$ when E7-expressing keratinocytes are induced to differentiate (Jones et al. 1997; Ruesch and Laimins 1998); PCNA is induced within these cells, and markers of terminal of differentiation are expressed. The abrogation by E7 of keratinocyte differentiation-associated CDKIs (Missero et al. 1995, 1996; Di Cunto et al. 1998) may be associated with its ability to maintain a replication-competent state while permitting the development of a differentiated environment compatible with viral late functions.

L1 and L2 ORFs

The products of the L1 and L2 ORFs are expressed in only the most terminally differentiated keratinocytes and form the viral capsid. The capsid comprises 360 molecules of L1, arranged as 72 capsomers, in an icosahedral surface lattice. Recombinant HPV11 L1 with cysteine-to-glycine mutations forms capsomeres but cannot assemble into capsid-like structures, suggesting that disulphide bonds mediate capsomere binding in the papillomavirus capsid (Li et al. 1998). Cryo-electron microscopy indicates that the L2 protein is situated at the center of pentameric capsomeres in mature virions (Trus et al. 1997).

A number of studies have demonstrated that L2 is required for encapsidation of viral genomes into infectious virions (Roden et al. 1996; Stauffer et al. 1998; Zhou et al. 1993). In the model for L2-mediated assembly of papillomavirus virions, L2 localization to subnuclear domains causes the subsequent recruitment of E2 with bound viral genome and L1 (Okun et al. 2001). This L2–L1–E2-genome association confers an appropriate environment and/or concentration of components for virion assembly. The E2-binding capacity of L2 is important to confer selective encapsidation of PV DNA, and hence this is another possible function of E2-binding sites within the viral genome. Given that virions containing E2 protein have not been detected, it is proposed that E2 acts catalytically in the process of DNA encapsidation during virion assembly.

CLINICAL ASPECTS OF HPV INFECTION

Nongenital skin warts

These are common benign proliferations that occur most frequently in children and young adults. The classification of cutaneous warts includes verruca vulgaris (common warts; Figure 8) verruca plana (plane warts), verruca plantaris (deep plantar warts), mosaic plantar warts, butchers' warts, and erythrodysplasia verruciformis. Although not absolute, each classification is associated with specific HPV types, clinical and histologic appearance, and prognostic features (Moore and

Figure 8 *Common wart showing the characteristic appearance of a rough keratotic papule. Lesions may be multiple or single on cutaneous surfaces, with the most common sites being the dorsal aspects of hands and fingers. Photograph courtesy of Dr Libby Edwards.*

Tyring 2001). Butchers and meat handlers have an unusually high prevalence of hand warts, most of which are caused by HPV-7 and attributed to the combination of maceration and trauma to which these workers are subjected. Studies of warts in children show that spontaneous regression will occur within 2 years in about 60 percent of cases; the remaining third show a spectrum of responses, but eventually most lesions resolve (Massing and Epstein 1963). Immunosuppression as a consequence of transplantation, malignant, or infectious disease (HIV) increases the incidence of skin warts. These lesions are larger, more persistent, and refractory to treatment than in immunocompetent individuals, and HPV types usually identified in Epidermodysplasia verruciformis (EV) (Table 3) are frequently detected in addition to the common cutaneous HPVs.

Epidermodysplasia verruciformis

EV is a genodermatosis and is an HPV-associated, lifelong, genetic disease (for review see (Majewski and Jablonska 2001). The warts appear in early childhood, become widespread, tend not to regress, and invasive cancers can develop from them (Figure 9). EV is an autosomal recessive condition and is associated with specific HPV types (Orth et al. 2001) (Table 3) that persist for life, generating clinical lesions that are

refractory to treatment. In the immunocompetent host, EV HPV types are present in a latent form in the skin but do not manifest themselves clinically unless the individual is immunosuppressed, in which case EV types can be identified in cutaneous neoplasms. Overall, the evidence indicates that the defect in EV is an inadequate cell-mediated immune response to the EV HPV subset. Consistent with this notion is the fact that cutaneous responses to contact sensitizers such as dinitrochlorobenzene (DNCB) are absent in EV patients. An important feature of the carcinomas in EV is that they develop on sun-exposed surfaces, suggesting that UV light is a cofactor in EV HPV viral oncogenesis.

Nonmelanoma skin cancer

Nonmelanoma skin cancer (NMSC) (basal cell carcinoma (BCC) and squamous cell carcinoma (SCC)) are the most prevalent malignancies in fair-skinned individuals worldwide. Epidemiologic studies have implicated HPVs in these cancers, particularly in those arising in immunosuppressed individuals (for review see Harwood and Proby 2002). Depending on the sensitivity of the assays HPV DNA can be detected in up to 80–90 percent of SCCs arising in transplant patients. EV HPV types predominate, but no specific HPV is associated with malignancy (Harwood and Proby 2002). The prevalence of HPV DNA in premalignant lesions such as keratoacanthomas, actinic keratoses, and carcinoma in situ in transplant patients can be as high as in SCCs. The same HPV types predominate in these lesions and in BCCs, although HPV prevalence is lower in the latter (Berkhout et al. 2000).

NMSCs in immunocompetent individuals also harbor HPV DNA but the prevalence is lower (0–50 percent for SCC, 31–44 percent for BCC). However, HPV DNA can be detected in normal skin biopsies in 30–35 percent of individuals, and EV HPV types predominate (Berkhout et al. 2000). Importantly, EV HPVs have been detected in benign hyperproliferative skin disorders such as psoriasis, where 90 percent of lesional skin biopsies contain HPV, particularly HPV-5 and HPV-36 (Favre et al. 2000). This raises the possibility that these associations are not causal but represent reactivation of latent HPV genomes in proliferating keratinocytes, and at present the evidence that HPV is the initiating factor in NMSC is inconclusive.

Aerodigestive tract

Papillomatosis can occur anywhere in the aerodigestive tract – the oral cavity, nasal sinuses, hypopharynx, larynx, bronchial tree, and esophagus. In the oral cavity HPV infection is associated with a range of benign proliferative lesions (Table 4), of which squamous papilloma caused by HPV-6 or -11 is the most common (Figure 10). HR-HPV types are detected in dysplasias and squamous cell carcinomas, but these types are also present in normal oral mucosa and the etiologic role of HPV in oral cancer is questionable. However, the high prevalence of HPV-16 and HPV-33 in tonsillar carcinomas does imply a causal role for HPV in these cancers, and there are some laboratory data to support this (Snijders et al. 1994).

Papilloma is one of the most common benign laryngeal tumors, but its prevalence is difficult to estimate. The incidence of recurrent respiratory papillomatosis (RRP) in children is estimated at 4.3/100 000, and among adults 1.8/100 000 (Derkay 1995). HPVs are the causal agent, with HPV-11 infections predominating followed by HPV-6, -16, and -18 (Dickens et al. 1991). Mixed infections are common. Histologically the lesions are benign, but morbidity is significant as recurrence and/or dissemination affect the patency of the airways. Clinical behavior is variable, and lesions may regress, persist, or progress to malignancy. The latter is cofactor dependent and smoking is a significant risk factor here. Treatment is usually endoscopic excision under magnification. The frequent recurrence and often confluent spread of these lesions make treatment difficult, and patients usually require multiple surgical interventions. Noninvasive effective therapies are desperately required for these individuals.

GENITAL TRACT INFECTIONS

HPV infection of the anogenital skin and mucosae results in lesions with two morphologies: anogenital

Table 4 *HPV types in benign lesions of the oral mucosa*

Lesion	HPV types found	
	Frequently	Infrequently
Normal mucosa	6, 11, 16, 18	7, 31, 33, 59, 61
Verruca vulgaris	2, 4, 57	1, 6, 11, 16

warts (condyloma acuminata) and squamous intraepithelial lesions (SIL). Condylomata are associated predominantly, but not exclusively, with infection by LR-HPV types and have a low to negligible risk of malignant progression (Table 3). SIL are associated with both low- and high-risk genital HPV types, and high-risk HR-HPV-infected lesions can progress to malignancy. The majority of epidemiologic studies have been focused on HPV infection in the lower genital tract of women, and relatively little is known about nongenital HPV infection and genital HPV infection in men. In women, genital HPV transmission is primarily by sexual contact after the sexual debut, and there is a strong positive trend between prevalence of infection and increasing number of sexual partners (IARC 1996).

Condyloma acuminata

External anogenital warts are the commonest viral sexually transmitted disease (PHLS Communicable Disease Centre 1989). They have been recorded as occurring at an incidence rate of 2.4 cases/1000, with a peak attack rate of 1.2 percent in men and women aged 20–24 years (Persson et al. 1996). The warts are usually exophytic, often mutiple lesions that can occur anywhere on the external genitalia, but are found mainly the perineum and anus in women (Figure 11a) and on the penis and anus in men (Figure 11b). Most lesions regress spontaneously over time if left alone, but in a fraction of infected individuals they can persist for years. They are more frequent in the immunosuppressed, and are refractory to treatment in these patients. Most lesions are caused by HPV-6, about 15 percent are attributable to HPV-11, and a tiny fraction to other HPV types, including HPV-16. Current treatments suffer from high recurrence rates, although trials with the immunomodulator Imiquimod report significantly reduced recurrences post-therapy (Edwards et al. 1998). A rare anogenital form of condyloma acuminata is the Buschke–Löwenstein tumor, which is locally invasive but nonmetastasizing. These lesions usually contain HPV-6 or -11, and rarely HPV-16 (Boshart and zur Hausen 1986).

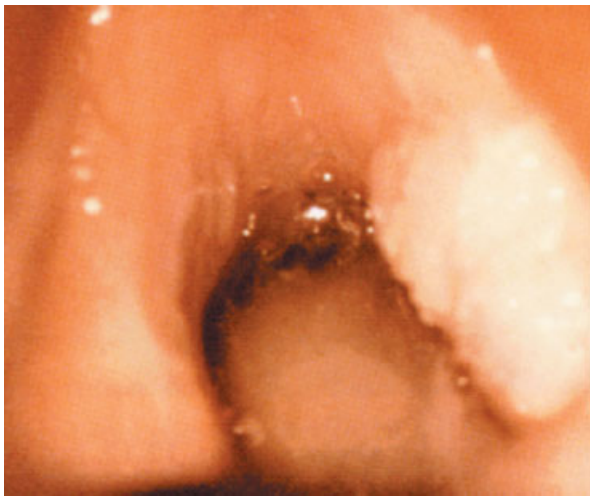

Figure 10 *Solitary adult-onset laryngeal papilloma, associated predominantly with HPV-11 (Gross et al. 1997, with permission).*

Squamous intraepithelial lesions and anogenital cancers

Squamous intraepithelial lesions (SIL) are classified histologically and form a distinct spectrum of histological atypia. Three grades of cervical intraepithelial neoplasia (CIN) are recognized in the European classification: CIN 1 – mild, CIN 2 – moderate, and CIN 3 – severe. The Bethesda classification for cytology used in the USA recognizes two classes: low-grade squamous intraepithelial lesions (LGSIL) (CIN 1) and high-grade squamous intraepithelial lesions (HGSIL) (CIN 2/3). In the vagina, vulva, penis, and anus a similar but not identical spectrum of changes can be identified – VAIN, VIN, PAIN, and PIN – but the likelihood of progression of these lesions to frank malignancies is still unclear. It is probable, but not unequivocally proven, that the majority of these intraepithelial lesions are a result of HPV infection. LGSIL at any site can be associated with both high- and low-risk HPV types, although high-risk types predominate. HGSIL are associated

almost exclusively with high-risk types. The gross appearance of low- and high-grade cervical SIL is shown in Figure 12.

The epidemiological evidence relating HPV infection to cervical cancer is very strong and the association is considered to be causal (IARC 1996). In all methodologically sound case–control series using reliable HPV DNA detection methods the association between HR-HPVs and cervical carcinoma or the high-grade precursor lesions is very strong with ORs over 15 (reviewed in (Muñoz and Bosch 1996). The strength of this association rules out the possibility of chance, bias, or confounding. Furthermore, the association is consistent, as equally strong associations are found in countries with a high or low incidence of cervical cancer (Muñoz et al. 1992). Reliable large-scale prospective data are available, and it is clear that infection with

Figure 12 *Intraepithelial lesions.* **(a)** *Low-grade cervical intraepithelial neoplasia seen as a raised white area on the posterior lip of the cervix; both low- and high-risk HPVs can be detected in these lesions.* **(b)** *High-grade intraepithelial neoplasia and invasive carcinoma of the cervix, associated with high-risk HPVs, particularly HPV-16 (Gross et al. 1997 with permission).*

HR-HPV types precedes the development of HGSIL (Schiffman and Brinton 1995). The epidemiological evidence alone indicates that more than 95 percent of cervical cancers are attributable to HPV infection (Walboomers et al. 1999). A summary of the natural history of cervical HPV infection is as follows:

- Transient genital HPV infections are quite common (prevalence about 11–20%) in young sexually active women;
- Most infections are subclinical and resolve. Most lesions are self limiting proliferations (LGSIL) and resolve;
- A minority of women develop persistent infections with focally high levels of DNA;
- Some of these persistent infections with high risk HPVs progress to HGSIL;
- Some HGSIL progress to carcinoma.

Mechanisms of genital HPV oncogenesis

As discussed above, experimental studies show that the *E6* and *E7* genes of the high-risk genital viruses encode oncoproteins that deregulate key controls in cell proliferation. E7 binds the retinoblastoma protein pRb, effectively blocking the transcriptional repressor function of this protein and overriding the G_1/S checkpoint of the cell cycle. The E6 of the HR-HPVs binds to p53 to form a stable complex which, in combination with E6-AP, undergoes ubiquitin-mediated proteolysis. The ability to form the E6–E6-AP–p53 complex seems to be restricted to the HR-HPVs. This interaction with p53 is crucial, compromising the ability of the cell to effect growth arrest in the face of DNA damage. As a consequence of these interactions cell-cycle checkpoints are bypassed, mutations may be accumulated, and the HPV-infected cell may acquire the immortal phenotype. However, malignant transformation is a rare consequence of infection with HR-HPVs, only a fraction of infected individuals progress to CIN 3, and only 30–50 percent of CIN-3 progress to invasive cancer. In the normal viral infectious cycle viral gene expression is tightly controlled and E6/E7 expression is confined to nondividing differentiated cells, where the oncogenic potential of these genes is not allowed to flourish. HPV oncogenesis requires the deregulation of viral and cellular gene expression so that early genes are inappropriately expressed in dividing cells. In cervical carcinomas and many HGSIL this deregulation is achieved by integration of the HPV genome into host chromosomes (Daniel et al. 1995; Schwarz et al. 1985).

TRANSMISSION

Transmission occurs primarily through person-to-person contact, with shedding of viral particles from the infected individual to microwounds on the skin or mucosa of a naïve recipient. Genital HPVs are transmitted primarily, but not exclusively, via sexual contact. There is evidence for transmission from the fingers in individuals who have genital warts (Strauss et al. 1999) and for vertical transmission of HPV-16 resulting in oral infection (Puranen et al. 1997). A history of genital warts is a risk factor for juvenile recurrent respiratory papillomatosis (Shah et al. 1998), suggesting intrapartum infection.

LABORATORY DIAGNOSIS

HPVs cannot be grown efficiently in tissue culture or in animal models. Diagnosis of HPV infection relies therefore on the direct detection of HPV genomes and/or gene products by molecular hybridization procedures, usually preceded by nucleic acid amplification, in fresh or fixed tissue biopsies, tissue scrapings, and exfoliated cells. HPV detection and typing are tests not routinely available in diagnostic laboratories.

Serology

Individuals infected with HPV do make a type-specific serum antibody response to the major viral capsid protein L1 (Nonnenmacher et al. 1995; Steele and Gallimore 1990). Virions are not available for ELISA, but L1 VLPs have been used widely as the target antigen in ELISA in seroepidemiologic studies (Stanley 1997). Unfortunately, owing to the highly variable interval between infection, lesion development and seroconversion, plus the relatively low sensitivity of the assay, the detection of anticapsid serum antibody is not useful in diagnosis in the individual patient.

IMMUNITY

HPV infections are common, but the immunopathogenesis of these infections is still poorly understood. The majority of studies have focused on genital infections, and it is clear that these are common in young sexually active individuals, the majority of whom apparently clear the infection without overt clinical disease. Those who develop warts or low-grade intraepithelial lesions also in most cases mount an effective cell-mediated immune response and the lesions regress. Nonregressing anogenital warts and LGSIL are not associated with inflammation or histological evidence of immune activity, but regression of anogenital warts is accompanied by a dense mononuclear cell infiltrate dominated by T cells and macrophages and a cytokine expression characteristic of a Th1 cell-mediated immune response (Coleman et al. 1994). Animal models support this and provide evidence that the response is regulated by $CD4^+$ T cell-dependent mechanisms (Nicholls et al. 2001). The

central importance of the $CD4^+$ T-cell population in the control of HPV infection is shown by the increased prevalence of HPV infections in individuals immunosuppressed as a consequence of either organ transplantation or HIV infection (Benton and Arends 1996). Although it seems clear that the $CD4^+$ T-cell subset is critical for the induction and regulation of the host response to HPV, the antigenic targets and the nature of the effector response are still not known unequivocally. Evidence from both animal models and human infections indicates that one of the dominant responses is to E2 antigens, but responses to other early proteins E6 and E7 have also been identified (Stanley, 2001b). There is increasing evidence that both NK cells and antigen-specific CTLs are important effectors, but these responses are poorly understood.

Neutralizing antibody to the L1 capsid protein accompanies the induction of successful cell-mediated immunity, and these responses are certainly protective against subsequent viral challenge in natural infections in animals, suggesting that vaccines inducing serum neutralizing antibodies to L1 will be protective (Stanley 1997). Prophylactic immunization with VLP subunit vaccines composed of the major capsid protein L1 of some of the genital HPVs are now in phase III clinical trials. The vaccines are immunogenic, inducing type-specific responses; they are safe and early results indicate efficacy (Koutsky et al. 2002).

If the cell-mediated response fails to induce lesion regression and viral clearance then a persistent viral infection results that is, in part, due to operational immune tolerance. This seems to be reflected by the detection in vitro, in persistently infected individuals, of enhanced cellular and humoral responses to early viral proteins but the failure to clear virus in vivo (de Gruijl et al. 1996a; de Gruijl et al. 1996b). The importance of the MHC in susceptibility to or protection from *Papillomavirus* infection and associated neoplastic disease is supported by data from animal models and clinical studies (Beskow et al. 2001), but this area remains a crucial one for further investigation. The increasing understanding of the mechanisms by which the host responds effectively to HPV infection, and the reasons for the failure of these defense mechanisms in a minority of circumstances, has led to the development of therapeutic immunologically based strategies targeted to both high- and low-risk viruses.

Human polyomaviruses	2		

INTRODUCTION

During the last 30 years polyomaviruses, in particular SV40, have been extensively utilized by molecular biologists to decipher complicated biological events including gene transcription, RNA processing, control of RNA translation, and DNA replication in eukaryotic cells. In recent years, these viruses have received special attention in the field of biomedical science due to their involvement and association with diseases in humans, ranging from demyelinating disorders and nephropathy to various types of cancers including brain tumors, lung malignancy, and lymphomas. These new developments have encouraged many biomedical and basic scientists to employ a variety of approaches and techniques to unravel the interaction of polyomaviruses with their specific host cells, and decipher the pathogenesis of the diseases associated with polyomaviral infection. Here, we have provided an overview highlighting the general features of polyomaviruses that include their structural organization, gene regulation, and replication prior to focusing our attention on three members of this group of viruses, JCV, BKV, and SV40, due to their increasing importance in the clinical setting. We further emphasize JCV due to its established association with the fatal demyelinating disease of the brain and its association with neural and nonneural malignancies.

GENERAL DESCRIPTION

Polyomaviruses have been isolated from a number of species including monkeys, rodents, and birds, as well as humans. The common feature of the members of the family *Polyomaviridae* rests on their unique morphology which includes a 45-nm icosahedral particle comprised of three capsid proteins, and their genome which consists of double-stranded circular DNA of approximately 5 000 nucleotides in size.

While productive infection with polyomaviruses is generally species-specific, expression of the viral genome appears to be less restricted and occurs in a broad range of species. Nevertheless, transcription activation of the viral promoter is tissue-specific for some members of the polyomavirus family. Humans are the established host for BKV and JCV, while primates, including rhesus monkeys, African green monkeys, baboons, and stump-tailed macaques are the hosts for simian virus 40 (SV40), lymphotropic papovavirus (LPV), simian agent 12 (SA12), and stump-tailed macaque virus (STMV), respectively. Detection of SV40 in several human tumors in recent years has raised the possibility of humans as co-hosts for this virus. Mice are the host for polyomavirus (PYV), while rabbits and hamsters are considered the hosts for rabbit kidney vacuolating virus (RKV), and hamster polyomavirus (HaPyV), respectively. Bovine polyomavirus (BPyV) and budgerigar fledgling polyomavirus (BFPyV) target cattle and birds, respectively. In general, polyomaviruses possess an oncogenic potential in several experimental animals and it is believed that the viral early protein plays a role in the oncogenicity of the virus.

In permissive hosts, lytic infection of the cells with polyomaviruses begins by binding of the virion to the cell surface proteins. For example, the association of SV40 with class I major histocompatibility complex is an early event for infection of monkey kidney cells with the

virus. Human polyomaviruses, such as JCV, however, appear to employ different cell surface receptors, most probably *N*-linked glycoprotein containing terminal α (2–6) linked sialic acid for its attachment to permissive cells (Atwood 2001). In either case, it is believed that the major capsid protein, VP1, plays a critical role in binding of the virus to its cell surface receptor. Once attached to the cell membrane, the virus internalizes through the process of endocytosis, and after uncoating, viral DNA appears in the nucleus. The viral DNA is present in a chromatin-like structure associated with cellular histone protein H2A, H2B, H3, and H4. The genome of the polyomavirus is divided into early and late regions on the basis of whether they are expressed before or after DNA replication. Viral proteins are encoded on both DNA strands and are transcribed divergently from a central regulatory region. The early genes encode the large and small tumor antigens, multifunctional proteins that regulate progression of the viral lytic cycle, and deregulate several important pathways in host cells. The small t- and large T-antigens have a common amino terminus and arise from alternatively spliced transcripts. In more recent studies, an altered isoform of T-antigen, named T′, has been detected in JCV infected cells (Frisque 2001). In SV40, a third protein named SELP, whose open reading frame is located in the leader of some early DNA species, has been reported yet its function remains unknown (Khalili et al. 1987b). Other polyomaviruses, including JCV and BKV, also possess an early leader open reading frame which exhibits greater than 50 percent homology with SELP. The late genes encode structural components of the viral capsid proteins, VP1, VP2, and VP3. VP1 is encoded by the 3′ end of the late region and is translated from a distinct mRNA in a different reading frame than the other two capsid proteins, VP2 and VP3. Both VP2 and VP3 are encoded in the 5′ end of the late region and are translated from a common mRNA. The VP1 mRNA leader sequence codes for a small protein named 'Agnoprotein' which is found only in SV40, JCV, and BKV polyoma species.

The full lytic infection cycle of polyomaviruses can be divided into two phases: the early phase occurs prior to viral DNA replication and the late phase, which includes all events such as viral DNA replication, expression of the viral late genes, assembly of progeny viral particles, and viral release. During the early phase, the virus attaches to the cell surface, enters the cell through endocytosis, transports to the cell nucleus and after uncoating, the viral early gene begins to transcribe and synthesize viral early RNA, and after translocation, the early proteins, T-antigen, and its various isoforms. Once T-antigen is accumulated in the nucleus of the cells, it cooperates with cellular DNA replication factors to stimulate viral DNA replication, and at the same time enhances the level of viral late gene expression. The products of the late genes including the capsid proteins, VP1, VP2, and VP3, enter the nucleus and participate in the assembly of viral progeny through the association of the viral capsid proteins with the newly synthesized viral DNA. One of the most intense areas of research on polyomaviruses has been on the regulation of viral gene transcription, cell type-specific activation of the viral genome, and the control of viral DNA replication. The DNA regulatory sequence which is responsible for transcription and replication of the viral genome spans the 400–500 nucleotides which are positioned between the viral early and late genomes.

This region is composed of many *cis*-acting regulatory motifs that provide targets for binding of cellular transcription factors. Of note, the transcription of polyomaviruses is dependent on the host transcriptional machinery. The association of the proper transcriptional factors with the viral DNA sequence potentiates RNA polymerase II and its subunits to initiate viral early gene transcription. Lengthy studies on the identification of cellular factors that stimulate the SV40 promoter led to the identification of several important proteins, such as Sp1 and the AP1 family, which exhibit a broad spectrum of regulatory functions upon eukaryotic gene transcription. It was also noted that the interaction of cellular proteins with the viral DNA sequence may not be sufficient for stimulation of viral promoters, suggesting that cross-communication and indirect interaction may play a critical role in viral gene expression.

HUMAN POLYOMAVIRUSES

JCV

The infection process of JCV, as of any nonenveloped small DNA virus, begins with the attachment of the viral particles to the cell surface receptors. Recent reports indicate that JCV enters the susceptible cells through clathrin-dependent endocytosis and α(2–3)-linked sialic acid appears to be critical in this process (Atwood 2001; Liu et al. 1998a,b; Pho et al. 2000). Subsequently, the viral genome is targeted into the nucleus by an unknown mechanism. Infectious virions are formed after DNA replication and expression of capsid proteins and finally, viral particles are released upon cell death.

The nucleotide sequence analysis of JCV genome has revealed that it is composed of three functional regions including the viral early coding region, the viral late coding region, and the viral noncoding regulatory region (Frisque et al. 1984) (Figure 1). Comparison of JCV sequences with two other closely related polyomaviruses, BK virus and SV40, has revealed that it exhibits extensive sequence homology in coding regions to its counterparts. However, the sequences within the regulatory region of JCV show the greatest degree of divergence from those of BK virus and SV40. Studies over the years have shown that the regulatory region of

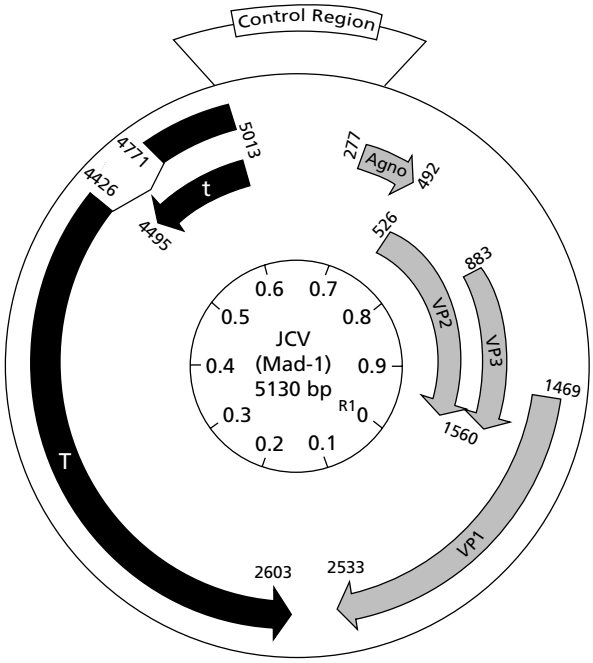

Figure 1 *Circular map of the JCV genome. Schematic representation of the JCV genome. Directions of the early and late coding regions are depicted with arrows. Early genes encode small t- and large T-antigens. Late genes encode the viral capsid proteins, VP1, VP2, and VP3, and Agnoprotein. The regulatory region is located between the two coding regions.*

JCV confers, at least in part, the tissue specificity of JCV gene expression (Ahmed et al. 1990a; Amemiya et al. 1989, 1992; Chowdhury et al. 1990, 1992, 1993; Khalili et al. 1988; Tada and Khalili 1992; Tada et al. 1989, 1991).

The regulatory region of JCV is composed of the origin of DNA replication, promoter elements for both early and late genes and *cis*-acting enhancer elements (Figure 2). The JCV origin of DNA replication is a 98-bp element located between the NF-κB motif and the first tandem repeat of JCV Mad-1 strain. It shows extensive homology to the SV40 origin (Frisque and White 1992; Kim et al. 2001). The enhancer elements are composed of two complete 98-bp tandem repeats (Mad-1 strain), each of which contains its own TATA box located in the early site of individual repeat. The first TATA box with respect to the origin of DNA replication is involved in the positioning of the transcription start sites for viral early genes (Frisque and White 1992; Kim et al. 2001; Lynch and Frisque 1990, 1991). The second TATA box does not appear to have a similar function for the viral late genes. The remaining regions within the 98-bp repeats have been shown to confer crucial *cis*-acting elements which were shown to serve as binding sites for several transcription factors (Frisque and White 1992; Kim et al. 2001; Major et al. 1992; Raj and Khalili 1995).

The regulatory region of JCV appears to be hypervariable in nature (Vaz et al. 2000; Yogo et al. 2001; Zoltick et al. 1995). Comparison of the regulatory sequences among a number of JCV isolates revealed that the hypervariability is mostly confined to 98 base pair tandem repeat region (Figure 2). Based on the variations including deletions and duplications, JCV isolates are classified into two classes or groups (Frisque and White 1992; Vaz et al. 2000; Yogo et al. 2001; Zoltick et al. 1995). The class I viruses are characterized by the presence of the 98-bp tandem repeat within its regulatory region. The Mad-1 strain of JCV belongs to class I. The class II viruses contain strains that exhibit variations from the regulatory region of the class I with deletions and insertions. Ninety-eight base pair repeats appear to vary in size and the distal repeat with respect to the origin of DNA replication lacks the TATA box sequences. There tends to be a full length or partial duplication of the 23-bp sequence element usually occurring at nucleotide 36 of the first tandem repeat (Frisque and White 1992). Although the mechanism by which these deletions and duplications occur and give rise to new strains of JCV remains unknown, it is generally

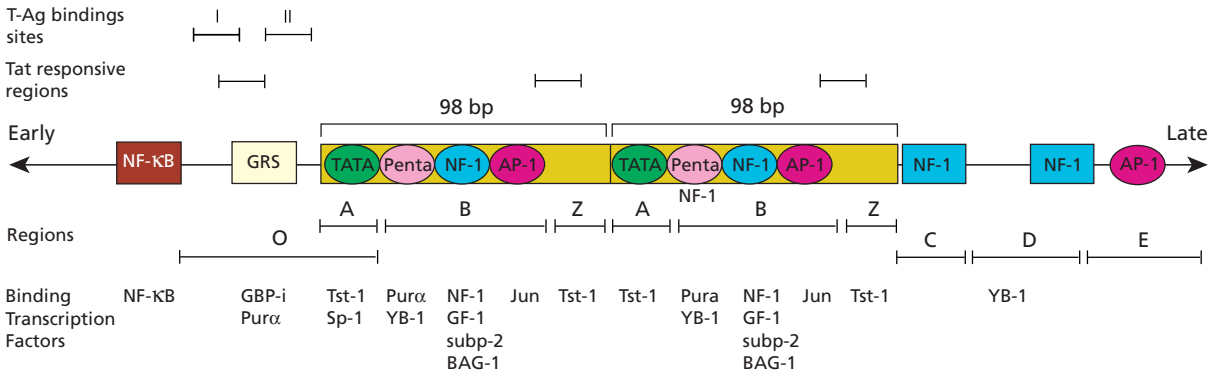

Figure 2 *Multiple transcription factor binding sites in the enhancer/promoter region of Mad-1. Transcription factors that have been shown to bind to the promoters are illustrated at the bottom of the schematic.* Cis*-acting elements are depicted in the boxes or circles in the schematic of the promoter. T-antigen binding sites and Tat responsive elements are indicated. Arbitrary subregions including A, B, Z, C, D, E, and O are indicated.*

accepted that both classes are derived from a common ancestral form of the JCV archetype strain which is mainly detected in the kidney (Gardner et al. 1971). It is postulated that alterations within the regulatory region of the JCV archetype strain can result in novel regulatory rearrangements of the virus with altered features. The new virus is then capable of replicating in new cells and tissues (Frisque and White 1992).

The Mad-1 strain of JCV has been used for most of the replication and transcriptional studies of JCV. As a result, the descriptions of the viral promoter-enhancer elements and the participation of these elements in viral gene transcription and DNA replication will be discussed with respect to Mad-1. In addition to containing the NF-κB motif and origin of DNA replication, the regulatory region of Mad-1 also confers two exact 98-bp tandem repeats (Figure 2) (Frisque and White 1992), which dictate the transcription of early and late genes in opposite directions. The *cis*-acting elements present within and around the 98-bp repeats were shown to be targets for tissue-specific and ubiquitous transcription factors (Figure 2). In addition to these cellular factors, the viral regulatory proteins, including large T-antigen and Agnoprotein, were also shown to regulate expression of the viral promoters (Raj et al. 1996; Safak et al. 2001, 2002). As stated earlier large T-antigen is a multifunctional phosphoprotein involved in both viral early and late gene expression, as well as in T-antigen-dependent viral DNA replication. Together with the cellular factors which are required for DNA replication, T-antigen binds to the viral origin of DNA replication, unwinds it and initiates replication bidirectionally (Lynch and Frisque 1990; Tavis and Frisque 1991). T-antigen regulates its own transcription via an autoregulatory loop, and plays a major role in the transcriptional switch from viral early to late gene expression (Khalili et al. 1987a; Lashgari et al. 1989).

The regulatory region of JCV is subdivided into arbitrary regions for the sake of simple transcriptional analysis (Figure 2). The cellular factors that interact with B region for example are extensively studied and include a 45 kDa protein (Khalili et al. 1988; Raj et al. 1998), GF-1 (Kerr and Khalili 1991), YB-1 (Raj et al. 1996), Purα (Chen et al. 1995), and AP-1 (Amemiya et al. 1992; Sadowska et al. 2003), Subp-2 (Fukita et al. 1993; Kerr and Khalili 1991), and BAG-1 (Devireddy et al. 2000). Computer-aided experimental analysis of the regulatory region have revealed the presence of multiple NF-1 binding sites included in the B, C, and D regions (Raj and Khalili 1995). The NF-1 transcription factor was shown to be involved in both viral transcription and replication (Kumar et al. 1993; Sock et al. 1993; Tamura et al. 1988, 1990). GF-1 is a partial recombinant protein cloned by Kerr and Khalili (1991) from a human fetal brain expression library and represents a human homologue of the cloned murine Sμbp-2 protein (Fukita et al. 1993). Its binding specificity is similar to that of NF-1. GF-1 was found to *trans*-activate viral early and late promoters (Kerr and Khalili 1991). YB-1 and Purα were shown to interact with this region. Recently, a novel Bcl-1-interacting protein, BAG-1, was cloned from p19 embryonic carcinoma cells using the JCV NF-1-binding site as a probe. It is expressed ubiquitously and regulates JCV early and late promoters through the NF-1 binding site (Devireddy et al. 2000). Another cellular factor that interacts with the B region is c-Jun, a member of the AP-1 family of transcription factors. The members of this family are known as the immediate–early inducible proto-oncogenes. Its binding activity to the B region appears to be modulated by NF-1 transcription factor which binds to adjacent NF-1-like sequences (Amemiya et al. 1992). It has been demonstrated recently that it interacts directly with its target sequences and activates transcription from the JCV promoters (Amemiya et al. 1992; Sadowska et al. 2003). Like AP-1, NF-κB, and GBP-i represent inducible cellular factors that modulate gene expression from viral early and late promoters. NF-κB represents a large family of transcription factors which are inducible in response to a wide variety of extracellular stimuli including the presence of phorbol esters and cytokines. The NF-κB family of proteins was shown to play a role in determining the basal and induced levels of transcription from viral early and late promoters (Ranganathan and Khalili 1993). While constitutively expressed subunits p50 and p52 activate transcription from the D domain (Raj et al. 1996), subunit p65 activates transcription from the NF-κB motif (Ranganathan and Khalili 1993). p50/p65 were also shown to indirectly influence JCV gene transcription through a 23-bp element present within the regulatory regions of many JCV variants (Safak et al. 1999). GBP-i interacts with GRS sequences and suppresses viral late promoter activity (Raj and Khalili 1994). Another regulator of viral early and late gene expression is the transcription factor Tst-1, a member of the well-characterized tissue-specific and developmentally regulated POU family of transcription factors. It was found to have distinct binding sites at A and Z regions. Tst-1 regulates viral early and late gene promoters by interacting with the A region (Renner et al. 1994; Wegner et al. 1993). In addition, the physical interaction of Tst-1 with JCV T-antigen was shown to lead to synergistic activation from both promoters (Renner et al. 1994). Even though a potential binding site for a ubiquitously expressed transcription factor, Sp-1, exists within the regulatory region of JCV, its function in the viral transcription is largely unknown. However, a polymerase chain reaction (PCR)-amplified variant of JCV was recently shown to confer a functional Sp-1 binding site. Transcriptional studies using Sp-1 as a *trans*-activator revealed that Sp1 stimulates transcription from the viral early promoter (Henson et al. 1992; Henson 1994). In addition to its own regulatory proteins, the JCV genome was also shown to be cross-

regulated by the regulatory proteins encoded by other viruses outside the polyomavirus family, including the HIV-1 Tat protein and the cytomegalovirus (CMV) immediate–early *trans*-activator protein 2 (IE2) (Tada et al. 1990; Winklhofer et al. 2000).

Compared to its counterpart, SV40, JCV exhibits a relatively long and inefficient lytic cycle which does not appear to conform with the progression of the viral illness, progressive multifocal leukoencephalopathy (PML). However, there is now experimental evidence to account for this discrepancy. In addition to its transcriptional regulation by a number of cellular factors and its own large T antigen, the JCV promoter has also been shown to be regulated by additional factors including cytokines, growth factors associated with immunosuppression, helper viruses such as human immunodeficiency virus type 1 (HIV-1) (Atwood et al. 1995; Tada et al. 1990), and cytomegalovirus (Heilbronn et al. 1993; Winklhofer et al. 2000). Growth factors and cytokines appear to mediate direct or indirect effects on viral promoters by induction of transcription factors, including GBP-i, NF-κB, and c-Jun (Raj and Khalili 1994; Ranganathan and Khalili 1993; Sadowska et al. 2003). An HIV-1-encoded transregulatory protein, Tat, was shown to transactivate the JCV promoter by interacting with two distinct regions within the viral regulatory region (Chowdhury et al. 1990, 1992, 1993; Tada et al. 1990).

NEUROTROPIC FEATURES OF THE JCV GENOME

Observations from both promoter-swapping experiments and somatic cell hybridization studies have indicated that the *cis*-acting promoter/enhancer elements of JCV and tissue specific cellular factors are the two main determinants that contribute to the narrow host range and neurotropism of JCV. The promoter/enhancer swapping experiments between SV40 and JCV in transgenic mice (Feigenbaum et al. 1992) and transfection studies in tissue culture indicated that narrow host range and cell specificity of JCV may be largely attributed to the JCV promoter/enhancer elements, as well as to the unique characteristics of JCV T antigen (Feigenbaum et al. 1987; Frisque and White 1992; Lashgari et al. 1989; Lynch et al. 1994; Tada et al. 1989). Reporter gene experiments using the regulatory region of JCV in in vivo and in vitro transcription assays (Ahmed et al. 1990a,b) indicated that expression of the viral early promoter is substantially higher in glial cells than nonglial cells, pointing to the importance of tissue-specific factors in JCV neurotropism (Ahmed et al. 1990b). However, JCV DNA replication and late gene expression can occur when large T-antigen is provided in nonglial cells (Lashgari et al. 1989). Somatic cell hybridization studies between transformed hamster glial cells expressing viral T antigen and mouse fibroblast cells supported the finding from transfection studies and suggested the presence of positive regulatory factors in glial cells and negative regulatory factors in nonglial cells (Beggs et al. 1988).

DISEASES ASSOCIATED WITH JCV INFECTIONS

Progressive multifocal leukoencephalopathy

PML is a white matter disease of the central nervous system resulting from the lytic infection of oligodendrocytes by JCV (Berger and Concha 1995; Major et al. 1992; Walker et al. 1973). The JCV archetype strain initially causes a latent infection in the kidneys. Immunosuppression of the host system due to an underlying disease, such as Hodgkin's lymphoma, lymphoproliferative disease, or acquired immune deficiency syndrome (AIDS) leads to the reactivation of the JCV archetype strain. During this reactivation period, the virus undergoes rearrangement in its regulatory region resulting in the Mad strains. The Mad strains then travel to the brain by an unknown mechanism, perhaps through B lymphocytes, and infect the myelin-producing cells of the central nervous system, the oligodendrocytes. Infection of oligodendrocytes results in the destruction of myelin, creating sporadic plaques of demyelination in the brain. Hence, demyelination occurs as a multifocal process, rarely unifocal, and develops in the white matter of the cortex, though plaques may also occur in any region of the central nervous system (CNS) including the brainstem and cerebellum, but excluding the spinal cord (Brooks and Walker 1984; Thomson and Jones 1968). Clinically, visual deficits are a common sign and symptom of PML at the time of presentation, accounting for 35 to 45 percent of cases, while motor weakness accounts for 25 to 33 percent of cases, and mental deficits (emotional liability, difficulty in memory, and dementia), account for 33 percent of cases at presentation (Berger and Concha 1995). PML usually progresses to death within 4–6 months. In occasional cases, clinical signs and symptoms appear to remain stable for a long period of time (Berger and Concha 1995; Major et al. 1992; Zoltick et al. 1995).

Historically, PML-like pathological cases were described by German pathologist Hallervorden as early as 1930 (Hallervorden, 1930) in a monograph entitled *Unique and non-classifiable processes*. However, the term PML was not crystallized as a distinct entity until the late 1950s. Astrom et al. described the illness in 1958 on the basis of its unique pathological features: demyelination, abnormal oligodendroglial nuclei, and giant astrocytes (Astrom et al. 1958). Descriptions made by these investigators were consistent with the development of a multifocal distribution of small or confluent white matter lesions in the cerebellum, basal ganglia, thalamus, and brain stem. Although the cause of these lesions was not known at that time, involvement of a virus in the pathogenesis of PML was suspected when inclusion bodies were seen in the nuclei of damaged

oligodendrocytes (Cavanaugh et al. 1959). Several years later, the use of electron microscopy for the identification of the suspected particles revealed that these particles resembled a polyomavirus in the enlarged nuclei of oligodendrocytes (Zu Rhein 1969; Zu Rhein and Chou 1965). Several attempts were made to isolate the suspect virus without success because of its unrecognized and unique biological properties, such as narrow host range and tissue specificity. In 1971, when Padgett and colleagues used brain tissue from a patient with PML as a source of innoculum in cell cultures derived from human fetal brain, they were successful in isolating a human polyomavirus from long-term cultures mainly consisting of glial cells (Padgett et al. 1971). This was the first direct evidence suggesting that a neurotropic viral agent was associated with the occurrence of PML. It was a coincidence that a virus similar in structure found in the urine of a patient who underwent a renal transplantation was also isolated at the same time (Gardner et al. 1971). Both viruses were associated with immunosuppressive states and named with the initials of donors, JC virus (JCV) for the patient with PML and BK virus (BKV) for the patient undergoing a renal transplantation.

Lytic infection of oligodendrocytes by JCV results in the destruction of the myelin-producing cells. The primary function of these glial cells is to myelinate the axons that project from the neuronal cell bodies of the overlying cortex. Destruction of these cells initially leads to microscopic lesions (Berger 2000; Major et al. 1992) (Figure 3b), but as the disease progresses, demyelinated areas become enlarged and eventually may coalesce, making them visible upon gross examination of cut sections (Astrom et al. 1958) (Figure 3a). In most cases astrocytes, the other component of glial cells, are also affected by infection exhibiting enlarged, lobulated, and bizarre looking nuclear structures (Major et al. 1992; Walker et al. 1973) (Figure 3b). Lipid-laden macrophages are frequently found in the areas of demyelination. Perhaps they are recruited into the CNS as a result of immune reactivation to phagocytize the myelin breakdown products. In most cases, due to the association of PML with AIDS, large numbers of HIV-infected macrophages are also found in extremely extensive necrotic lesions (Berger et al. 1987). It is not clear, however, how these immune cells infiltrated the areas of demyelination. One possible explanation is that JCV infection may recruit HIV-infected macrophages into the demyelinated areas or alternatively, uninfected macrophages may become infected by HIV after they are recruited into the nervous system.

Association of JCV with cancer

JCV causes tumors in experimental animals It is well established that polyomaviruses including JCV, BKV, and SV40 induce a variety of tumors in experimental animals (Krynska et al. 1999a; London et al. 1978, 1983; Varakis et al. 1978; Walker et al. 1973). They have the ability to induce neoplastic cell transformation in tissue culture as well. Shortly after its isolation from a brain tissue sample of a PML patient, JCV, like SV40, was confirmed to have tumorigenic potential in tissues of neuronal origin (Varakis et al. 1978; Walker et al. 1973). In this line of experiments, inoculation of JCV into several experimental animals resulted in a variety of tumors depending on the animal type, age, and site of inoculation. For example, more than 80 percent of newborn Syrian hamsters when inoculated intracerebrally and subcutaneously with the Mad-1 strain of JCV developed medulloblastomas, glioblastomas, and neuroblastomas (Varakis et al. 1978; Walker et al. 1973). In addition, the presence of an entire biologically active JCV genome was demonstrated when cells from these tumors were cocultivated with permissive glial cells (Walker et al. 1973). In another experiment, JCV was inoculated intraocularly into newborn hamsters. Abdominal neuroblastomas were developed in some cases. Metastases occurred to the bone marrow, lymph nodes, and liver (Walker et al. 1973).

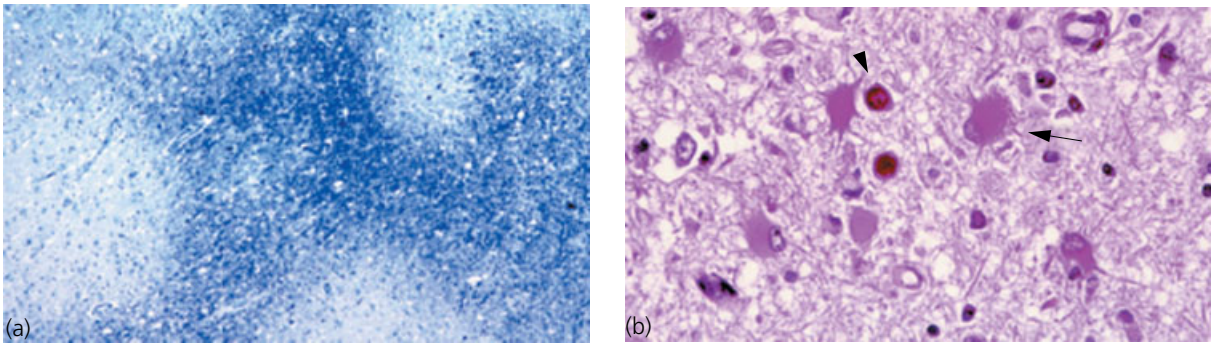

Figure 3 *Histopathological examination of a progressive multifocal leukoencephalopathy case.* **(a)** *A special staining for myelin demonstrates several areas of myelin loss in the white matter (Luxol Fast Blue, original magnification ×40).* **(b)** *Enlarged transformed astrocytes (arrow), and oligodendrocytes harboring intranuclear inclusion bodies (arrowhead) are present within the demyelinated plaques (hematoxylin-eosin, original magnification ×400).*

Interestingly, unlike the other members of the polyomavirus family (BK virus and SV40), JCV was shown to have the potential to induce tumors in nonhuman primates, i.e. monkeys. In order to mimic a case resembling PML in humans, owl and squirrel monkeys were inoculated with JCV subcutaneously, intraperitoneally, or intracerebrally (London et al. 1978, 1983). After inoculation, animals developed tumors at varying time intervals. For instance, one owl monkey developed a malignant cerebral tumor similar to an astrocytoma seen in humans 16 months after inoculation. Another developed a malignant neuroblastoma 25 months after inoculation.

Transgenic mice were used to mimic the acute demyelination seen in PML-affected brain tissue. In this line of experiments, a transgenic mouse line was created with the regulatory and coding sequences for JCV T-antigen (Small et al. 1986b). Some of the offspring from this transgenic mouse exhibited a mild to severe tremor phenotype. Hypomyelination and dysmyelination were observed in the CNS, but not in the peripheral nervous system. In addition, dysmyelination was further characterized in transgenic mice by Trapp et al. (1988) by examining the expression of JCV T-antigen and myelin-specific genes. Initial examination of brains from transgenic mice revealed that the amount of myelin sheath wrapped around the axons was relatively low. The expression levels of proteolipid protein (PLP), myelin basic protein (MBP), and myelin-associated glycoprotein (MAG) genes appeared to be normal. However, respective protein levels for each gene were shown to be reduced. Although the mechanism by which T-antigen plays a critical role in the reduction of respective protein levels in the brain of transgenic mice remains unknown, several suggestions were made in this regard. T-antigen may exert its function by altering the levels of both proteolipid and myelin basic protein synthesis or by inhibiting the maturation of oligodendrocytes. Additionally, JCV T-antigen may mediate its tumorigenic potential through its interaction with tumor suppressor genes, such as p53 and retinoblastoma gene products, Rb. Consequently their functions appear to be disturbed by the presence of T-antigen in the cell cycle. Coimmunoprecipitation assays using cellular extracts from JCV-transformed glial cells have revealed that JCV T-antigen forms complexes with Rb, p53, and p107 (Monier 1986). Supporting these findings, a report by Rencic et al. (1996) suggests a role for T-antigen in the induction of an oligoastrocytoma in an immunocompetent patient. This group also described the formation of different tumors in tissues derived from neuronal origin in transgenic mouse models (Franks et al. 1996; Gordon et al. 2000; Krynska et al. 1999a). The JCV early gene, large T-antigen, under the control of its own promoter was utilized to create these transgenic animal models. Histological and histochemical analysis of the tumor masses revealed the expression of the JCV oncogenic protein large T-antigen in tumors but not in control tissues. Oddly, transgenic animals created with the early region of JCV archetype strain (Krynska et al. 1999a) did not show any sign of hypomyelination in the central nervous system that is a feature that was seen with a transgenic animal created by Small et al. (1986b). On the contrary, cerebellar tumors which resemble human medulloblastomas were induced in those transgenic animals (Krynska et al. 1999a). In another transgenic line, half of the animals developed large, solid masses within the base of the skull by 1 year of age. Histological evaluation of the tumors by location and immunohistochemical studies demonstrated that these tumors arose from the pituitary gland (Gordon et al. 2000).

Detection of JCV in human tumors In addition to the induction of tumors in experimental animals, the JCV genome has also been detected in a variety of human tumors, which increases the likelihood of the involvement of JCV large T-antigen in tumor formation. In fact, Richardson, who first described PML (Richardson 1961), reported an incidental case of oligodendroglioma in a patient with concomitant chronic lymphatic leukemia and PML. Following this report, several more cases describing the concomitant occurrence of PML with different human tumors were also reported. Sima et al. reported the association of PML with multiple astrocytomas in 1983 (Sima et al. 1983). Similarly, Castaigne et al. (1974) described a case where a patient with a long history of immunodeficiency syndrome, in addition to PML, showed numerous foci of anaplastic astrocytes. Examination of the demyelinating lesions by electron microscopy demonstrated the presence of viral particles in both oligodendrocytes and astrocytes within PML foci, but not in the neoplastic astrocytes (Castaigne et al. 1974). A recent report by Shintaku and colleagues revealed dysplastic ganglion-like cells in a patient with PML (Shintaku et al. 2000). A large number of dysplastic or dysmorphic cells which showed properties of neurons were detected in the cerebral cortex. The expression of JCV large T-antigen, but not the viral capsid proteins, was detected in the infected neurons.

In addition to the cases of concomitant PML and cerebral neoplasm, JCV has been shown to be associated with human brain tumors in the absence of PML lesions. Boldorini et al. reported the detection of JCV DNA in the brain tumors of an immunocompetent patient with a pleomorphic xantoastrocytoma (Boldorini et al. 1998). Detection of JCV viral DNA and expression of large T-antigen were reported by Rencic et al. in tumor tissue from an immunocompetent HIV-negative patient with an oligoastrocytoma (Rencic et al. 1996). These two cases demonstrated the association of JCV in brain tumors of immunocompetent non-PML patients. Such findings further prompted attempts to establish the association of JCV with different types of brain tumors

in humans. Analysis of multiple brain tumors for the detection of JCV genome revealed that 57.1 percent of oligodendrogliomas, 83.3 percent of ependymomas, 80 percent of pilocytic astrocytomas, 76.9 percent of astrocytomas, 62.5 percent of oligoastrocytomas, and 66 percent of anaplastic oligodendrogliomas contained JCV early gene sequences (Del Valle et al. 2001, 2002a). Further, the JCV genome has been repeatedly detected in pediatric cerebellum tumors, medulloblastomas, and the viral early protein and the late auxiliary protein, Agnoprotein have been detected in tumor cells (Figure 4) (Del Valle et al. 2002b; Krynska et al. 1999b).

JCV genomic DNA has also been detected in tumor tissues that arise from other than neural origin. Recent reports indicate that the JCV genome is detected in the gastrointestinal tract and solid non-neural tumors such as colorectal cancers (Enam et al. 2002; Laghi et al. 1999; Ricciardiello et al. 2000, 2001).

BKV

Similar to JCV, BK virus (BKV) is widespread in the human population. Greater than 80 percent of the world's population is seropositive for viral proteins. The BKV genome is composed of 5 153 nucleotides and has a typical polyomavirus genomic organization. BKV shares greater than 75 percent sequence identity with JCV, with great divergence within the 300–500-bp noncoding regulatory region. The control region of BKV exhibits sequence variation among the various isolates as a result of nucleotide insertions, deletions, and rearrangements. The control region of the BKV archetype spanning a 375-bp sequence is comprised of several regulatory motifs serving as the potential binding site for regulatory proteins such as Sp1, NF-1, NF-κB, c-Jun, AP1, and many others. These elements are scattered within five arbitrarily divided regions named O (142 bp), P (68 bp), Q (39 bp), R (63 bp), and S (163 bp). In a typical BKV serotype 1 Dunlop strain, the control region is comprised of O (142 bp), three imperfect P regions: P (68 bp), P (50 bp), P (64 bp), and S (63 bp). It is postulated that rearrangement in the control region alters the architectural organization of the viral enhancer/promoter permitting efficient expression of the viral genome in the host. Lytic infection of BKV begins with the expression of the early genome whose product, T-antigen, orchestrates viral DNA replication and late gene activation. Similar to JCV, primary infection with BKV is usually asymptomatic and occurs during childhood with the highest incidence of transmission between the ages of 1 and 6 years. While the route of infection has not been well established, the association of mild upper respiratory illness and tonsillitis during exposure to the virus and subsequent seroconversions have led to speculation that the upper respiratory tract is the route of primary infection with BKV. After primary infection, BKV is likely distributed to all organs via peripheral blood cells and establishes a harmless latency, most notably in the kidney. Reactivation of BKV has been observed in the urinary tract under certain physiological conditions such as pregnancy; kidney, bone marrow, and heart transplantation; immunodeficiency disorders; systemic lupus erythematosus; and immunosuppressive therapy. After reactivation of BKV, an inflammatory syndrome affecting several organs has been detected. It is hypothesized that changes in the immune system and other physiological conditions cause dysregulation of cytokines and immunomodulators that lead to potentiation of transcriptional factors and/or suppression of transcriptional inhibitors that are involved in the control of BKV enhancer/promoter activities. Supporting this notion, it was demonstrated that interaction of nuclear factor (NF-1) with its target sequence within the BKV

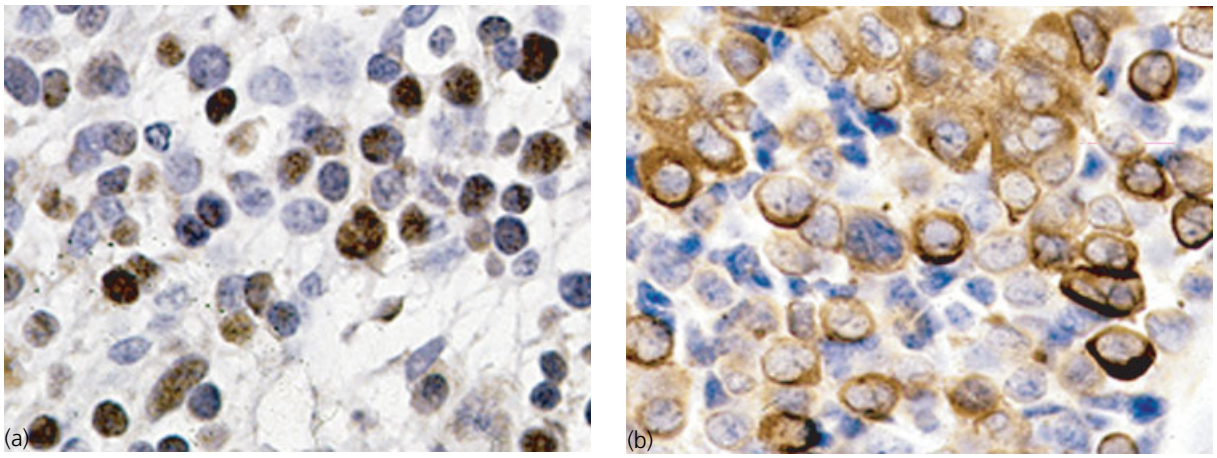

Figure 4 *Immunohistochemical detection of JC viral proteins, T-antigen and Agnoprotein in human medulloblastomas: High magnification view of a human medulloblastoma, demonstrates the presence of T-antigen in the nuclei of approximately 60 percent of the neoplastic cells (***(a)** *T-antigen 1:100 dilution, original magnification ×100). When tested with an anti-Agno antibody the cells show a robust cytoplasmic immunoreactivity (***(b)** *Agno 1:2 000 dilution, original magnification ×100).*

promoter results in suppression of viral late transcription. The presence of NF-κB, on the other hand, suggests a role for NF-κB inducible pathways via the p50/p65 transcription factor upon stimulation of cells with various tumor necrosis factors, cytokines, and immunomodulators, such as TNF-α and IL-2. Also, activation of the viral promoter can occur upon hormonal imbalances; the presence of estrogen responsive and glucocorticoid responsive elements suggest activation of BKV gene transcription by estrogen-induced transcription factors. During pregnancy, maximum reactivation of the virus is observed during the third trimester when the levels of estrogen and progesterone are at their highest, pointing to a role for glucocorticoid responsive element (GRE) and estrogen responsive element (ERE) in the induction of BKV gene transcription.

BKV AND HUMAN DISEASES

Hemorrhagic cystitis and nephritis

Reactivation of BKV and its appearance in urine is frequently observed in pregnant women without any sign of illness. Considering the kidney as a primary site for BKV reactivation, much attention has been focused on the role of BKV in renal allograft dysfunction and failure. BKV-associated nephropathy (BKVN) ranges from asymptomatic hematuria to hemorrhagic cystitis in renal graft transplants, as well as in patients with bone marrow transplantation (Andrews et al. 1988; Bedi et al. 1995; Bogdanovic et al. 1998; Chan et al. 1994; Coleman et al. 1973; Vögeli et al. 1999). In addition, BKV-associated ureteric stenosis and tubulointerstitial nephritis has been reported in individuals with renal allograft transplantation (Coleman et al. 1978; Gardner et al. 1971, 1984; Mathur et al. 1997; Nebuloni et al. 1999; Pappo et al. 1996; Purighalla et al. 1995; Smith et al. 1998). Hemorrhagic cystitis associated with BKV has also been seen in AIDS patients (Gluck et al. 1994). It has been speculated that treatment of recipients of renal allograft transplants with immunosuppressive drugs leads to reactivation of latently infected BKV in the donated organs. The reactivation of BKV that is histologically observed by areas of by tubular necrosis is in concurrence with the loss of organs. While there is no direct evidence for the induction of nephropathy by BKV in humans, earlier observations from experimental animals is consistent with the assumption that BKV is able to induce nephropathy in humans. According to that observation, a member of the polyomavirus family named cynomolgus polyomavirus induces interstitial nephritis, ureteritis, and enteritis, the symptoms which are seen in BKVN in immunosuppressed cynomolgus monkey (Van Gorder et al. 1999).

Reactivation of BKV and renal tubular injury has been repeatedly observed among AIDS patients. The clinical symptoms caused by BKV activation in AIDS patients includes meningoencephalitis, retinitis, and nephritis (Bratt et al. 1999; Nebuloni et al. 1999).

While there is no established treatment for patients with BKV-associated renal disease, it is believed that a decrease in the doses of immunosuppressive drugs in patients who undergo kidney allograft transplantation may result in viral clearance.

Association of BKV with cancer

BKV causes tumors in experimental animals Similar to its close family member JCV, BKV is tumorigenic in several experimental animals. For example, intracerebral or intravenous inoculation of BKV in hamster results in the genesis of a broad range of tumors, such as ependymoma, neuroblastoma, pineal gland tumors, fibrosarcoma, osteosarcoma, and tumors of pancreatic islets (Corallini et al. 1977, 1978, 1982; Costa et al. 1976; Dougherty, 1976; Greenlee et al. 1977; Nase et al. 1975; Noss and Stauch 1984; Noss et al. 1981; Shah et al. 1975; Uchida et al. 1976; van der Noordaa 1976). Inoculation of BKV in rats and mice caused formation of fibrosarcoma, liposarcoma, osteosarcoma, glioma, choroid plexus papilloma, and nephroblastoma (Corallini et al. 2001; Noss and Stauch 1984; Noss et al. 1981). It is believed that the oncogenicity of BKV is due to the expression of T-antigen, which has a transforming activity in cell culture. The evidence for the involvement of BKV T-antigen in tumorigenicity of the virus stems from a study in transgenic mice in which the affected animals expressing BKV T-antigen developed renal tumors, lymphoproliferative disease, and hepatocellular carcinoma (Dalrymple and Beemon 1990; Small et al. 1986a). The T-antigen of BKV has the potential to associate with tumor suppressors such as p53 and the pRb family to functionally inactivate these important cell cycle regulatory proteins (Dyson et al. 1989, 1990; Harris et al. 1996; Kang and Folk 1992; Shivakumar and Das 1996). In addition to its role in the deregulation of cell cycle pathways, BKV T-antigen may be involved in genomic instability and random chromosomal abnormalities. While the mechanism whereby BKV T-antigen induces chromosome aberrations remains unknown, several characteristics of the protein, such as the ability of T-antigen to associate with topoisomerase I, p53, and helicase activity may contribute to this event. Indeed, other viral proteins, including small t-antigen and the late regulatory protein, Agnoprotein, may also play a role in the tumorigenicity of BKV, as well as its ability to cause chromosomal damage.

Detection of BKV in human cancer The oncogenic potential of BKV in several experimental animals, the transforming activity of BKV T-antigen in vitro, and its tumorigenicity in transgenic animals prompted many investigators to search for the presence of BKV in various human tumors. Examination of 74 human brains

by conventional hybridization techniques revealed the presence of episomal free DNA of BKV in 19 samples (Corallini et al. 1987a). BKV DNA was also detected in significant numbers (44 percent) of tumors in pancreatic islets (Corallini et al. 1987b). In recent years, the search for the presence of BKV DNA in several laboratories using more sensitive assays, i.e. PCR, revealed the presence of BKV DNA in 50 out of 58, 74 out of 83, and 18 out of 18 brain tumors (De Mattei et al. 1995; Flaegstad et al. 1999; Martini et al. 1996). Using the same techniques, other laboratories failed to detect BKV DNA in ten brain tumor samples (Völter et al. 1997). The brain tumors which were studied included ependymomas, meningiomas, glioblastomas, gliomas, neuroblastomas, oligodendrogliomas, spongioblastomas, choroid plexus papillomas (Corallini et al., 1977, 1987b; De Mattei et al. 1994, 1995; Dörries et al. 1987; Negrini et al. 1990). While there is no established role for BKV in human neoplasia, it is evident that studies to establish a correlation between BKV and tumors of the central nervous system and urinary tract are essential.

SV40

SV40 represents the most studied member of the family *Polyomaviridae*. Originally isolated from monkeys, in recent years it has been repeatedly detected in a selected group of human tumors. The control region of SV40, responsible for transcription of the viral early and late genome, is comprised of three 21 base pair GC-rich repeats and two 72-bp tandem repeats with multiple binding sites for DNA binding transcription factors. A TATA box positioned in front of the GC-rich motif provides a site for the formation of a transcription initiation complex. By utilizing the SV40 regulatory sequence as a model for studying regulation of eukaryotic promoters, investigators were able to discover several key general transcription factors such as the families of Sp1, AP1, etc., to decipher complicated events involved in the initiation and elongation of the transcription process. The origin of viral DNA replication is located near the TATA box and contains the core origin and the auxiliary sequences which enhance the efficiency of viral DNA replication. The interaction of the viral early protein, T-antigen, with the sequences surrounding the origin of DNA replication is pivotal for the start of viral DNA replication indicating that expression of the early genome is the first step in the lytic cycle of SV40.

The early genome of SV40 has two transcription units that are transcribed from a region near the origin of DNA replication (Khalili et al. 1986). The early–early (E_E) transcription unit whose RNA is responsible for production of large and small T-antigen predominates at the early times after infection. The late–early (L_E) transcription unit whose RNA start sites are located upstream of the E_E TATA box, have coding sequences for both small t- and large T-antigen, and a small 2–7 kDa protein, the SV40 early leader protein (SELP) (Khalili et al. 1987b). The L_E transcription unit functions at late times after infection, and while the function of SELP remains to be investigated, it is evident that transition of the sites of early RNAs from E_E to L_E position results in the inclusion of two AUGs in the leader of the RNA. These additional AUG decrease the utilization of the AGG which is responsible for T-antigen production, thus bringing additional steps to regulate early gene transcription at the translational level. The large T-antigen of SV40 has a modular structure with several biological activities including ATPase, DNA helicase, DNA-binding, and protein-binding activities. Large T-antigen can undergo post-translational modifications, events that could potentiate its function upon the viral life cycle and/or host-cell behavior.

Replication of viral DNA is a complicated process that requires a functional origin of replication, large T-antigen with its DNA binding and helicase activities, and the host replication machinery. DNA replication usually occurs between 4 and 8 h after infection and is followed by the enhanced transcription of the late region of this virus. Results from a large volume of molecular studies have revealed that direct and indirect association of T-antigen with several cellular transcription factors is involved in the replication of viral late gene expression. Once the viral late proteins are produced, consistent with the general scheme of polyomaviruses, the assembly of the virion occurs in the nuclei of the cells.

SV40 AND HUMAN DISEASE

It is believed that the introduction of SV40 into the human population is related to the development and distribution of poliovaccines. Evidently, the initial preparations of poliovaccines that were inadvertently contaminated with SV40 caused exposure of hundreds of millions of persons to the virus. It is estimated that more than 98 million people in the United States who received poliovaccine between 1955 and 1963 were exposed to SV40 (Shah and Nathanson 1976). Other poliovaccine preparations using adenovirus types 3 and 7, which were utilized between 1961 and 1965, were also contaminated with SV40 (Lewis et al. 1973). In light of cell culture studies showing the transforming ability of SV40 T-antigen and results from animal experiments verifying the oncogenicity of T-antigen, the observed distribution of SV40 in a large population of humans via the poliovaccine has become an important subject in cancer development in humans.

SV40 caused tumors in experimental animals

In 1962, several laboratories demonstrated that SV40 can induce tumors in Syrian hamsters (Eddy et al. 1962; Girardi et al. 1962). The type of tumors induced by

SV40 was dependent on the route of viral inoculation. Systemic inoculation of SV40 resulted in the development of mesotheliomas, osteosarcomas, and lymphomas, while intracranial inoculation of hamsters with SV40 led to the development of brain tumors, such as ependymoma, and subcutaneous inoculation caused soft tissue sarcoma. Transgenic mice containing the SV40 early genome developed choroid plexus papilloma in which T-antigen expression was detected.

SV40 and human tumors

Results from many studies in recent years point to the possible role of SV40 in cancer development in humans (Gazdar et al. 2002). The first evidence of the association of SV40 with human cancer was presented in 1974 (Soriano et al. 1974) in a patient with metastatic malignant melanoma in which viral proteins were present in the lung, liver, and muscle metastases, but not normal tissues. Subsequently, SV40 has been detected by standard Southern blot and gene amplification in adult, as well as pediatric tumors of the brain including choroid plexus, ependymomas, and medulloblastomas (Bergsagel et al. 1992; Huang et al. 1999; Lednicky et al. 1995).

In one study the presence of SV40 DNA sequences has been reported in 32 percent of osteosarcomas and 41 percent of several other tumors (Carbone et al. 1996). Perhaps the most studied cases related to SV40 and cancer are malignant mesotheliomas in which nearly half of the cases contain the viral genome (Bocchetta et al. 2000; Carbone et al. 1994, 2002; Cicala et al. 1993; Rizzo et al. 1999, 2001; Shivapurkar et al. 1999, 2000; Testa et al. 1998; Toyooka et al. 2001). In the most recent studies, the SV40 sequence has been found in non-Hodgkin's lymphomas (Shivapurkar et al. 2002; Vilchez et al. 2002). Continuous detection of SV40 DNA in certain human tumors suggests that this DNA tumor virus has the ability to play a role in human disease. The inactivation of several tumor suppressors, deregulation of the cell cycle, and several other signaling pathways can serve as a potential path for the genesis of cancer by SV40 in experimental animals and perhaps in humans as well.

CONCLUDING REMARKS

The polyomaviruses have a long history of being utilized as a tool to decipher the interaction of viruses with their host cells, and to investigate pathways involved in the regulation of eukaryotic gene expression, mRNA translation, and DNA replication. Further, the polyomavirus early protein, such as SV40 T-antigen in the early years of the 'fight against cancer' has provided critical insight into the mechanism involved in the development of neoplasia. More recent studies from several basic science laboratories along with clinical observations have brought polyomaviruses to center stage in medical virology due to their involvement in various human diseases as outlined in this chapter. It is, therefore, essential to once again pay special attention to these viruses, and by employing more novel approaches and technology, study the various cellular events that can occur upon infection. The outcome will provide a better understanding of the pathogenesis of diseases associated with polyomaviruses. This information will facilitate development of effective antiviral drugs and vaccines for the prevention and treatment of diseases associated with polyomaviruses.

Herpesviruses: general properties

ANDREW J. DAVISON AND J. BARKLIE CLEMENTS

Introduction	1	Genome structure	5
Classification	1	Genetic content	6
Morphology and structure	3	Gene function	11
Replication	3	References	15

INTRODUCTION

The involvement of herpesviruses in a range of prominent medical or veterinary diseases makes them one of the most important virus families. Their ubiquitous occurrence, genetic complexity, evolutionary diversity, and widely differing biological properties have motivated great research effort worldwide, so that our understanding of these agents is now considerable. This is particularly apparent in the area of molecular genetics, and we can expect the knowledge gained to be applied increasingly to key questions about herpesvirus biology and to the development of effective therapies.

In this overview, we have focused on the best characterized member of the family, herpes simplex virus type 1 (HSV-1). Although a number of properties are shared by herpesviruses, many are not. For this reason, we have included pertinent information on the other human herpesviruses and, in a few cases, herpesviruses with nonhuman hosts. In this review, it is impossible to develop a comprehensive bibliography for such a vast area of research. Consequently, we have chosen to describe the accepted picture without extensive citation, instead referring to reviews and a limited selection of seminal or recent research papers.

CLASSIFICATION

The family *Herpesviridae*

The family *Herpesviridae* comprises over 120 viruses that infect a wide range of vertebrates, including fish, amphibians, reptiles, birds, marsupials, and other mammals including humans, and at least one invertebrate, the oyster (Minson et al. 2000). These viruses are ubiquitous and highly successful parasites, but each is usually restricted in natural infection to a single species and spreads from host to host by direct contact or by the respiratory route. Herpesviruses have large enveloped virions containing double-stranded linear DNA genomes that exhibit considerable diversity of size and structure. They vary greatly in their pathology and biology, but one common feature is their ability, following primary infection, to establish lifelong latent infections that can recrudesce to cause a second round, or even recurrent rounds, of disease. Herpesviruses are well adapted to their hosts, and it is not uncommon for primary or recurring latent infections to be inapparent or trivial in the natural setting. Under certain conditions, however, particularly those resulting in a degree of immune suppression, herpesviruses can be life-threatening. Several herpesviruses have also been implicated in various types of cancer.

On the criteria of host range, duration of reproductive cycle, cytopathology, and characteristics of latent infection, mammalian and avian herpesviruses have been divided into three subfamilies: the *Alpha-*, *Beta-* and *Gammaherpesvirinae*. Each subfamily is subdivided: for example, subfamily *Gammaherpesvirinae* comprises the *Lymphocryptovirus* and *Rhadinovirus* genera. In this review, however, we have also employed a simplified terminology used widely in the literature; for example, using α-herpesvirus (subfamily) and α_1-herpesvirus (genus) instead of *Alphaherpesvirinae* and *Simplexvirus*.

The herpesvirus nomenclature recommended by the International Committee on Taxonomy of Viruses (ICTV) uses the taxonomic unit to which the natural host belongs followed by a number. This rational scheme is used for many herpesviruses, but most human herpesviruses are generally known by their common names.

Alphaherpesvirinae exhibit a variable host range in cell culture, have a short growth cycle, spread rapidly with efficient destruction of infected cells and are neurotropic in that they have the capacity to establish latent infections primarily in sensory ganglia. *Betaherpesvirinae* are typified by a narrow host range and a long reproductive cycle in cell culture with slow virus spread. Infected cells frequently become enlarged and carrier cultures may be established. Viruses may become latent in secretory glands and lymphoreticular cells. *Gammaherpesvirinae* are associated with lymphoproliferative diseases in their natural hosts, and infect lymphoblastoid cells in vitro. Some cause lytic infections in certain epithelial and fibroblastoid cell lines. Viruses are specific for B or T lymphocytes, in which infection is frequently arrested without production of infectious progeny, and latent virus may be found in lymphoid tissue. The term 'lymphotropic' has been used to describe these viruses, but this is arguably a misleading term as lymphocytes are at best semipermissive.

This classification scheme, which is based predominantly on biological features, has been largely vindicated by studies of genetic relationships deduced from analyses of DNA sequence data. Genetic data have now superseded biological properties for classifying herpesviruses.

Human herpesviruses

To date, eight different herpesviruses have been identified whose natural host is humans (Table 1), all but two of which (HSV-2 and HHV-8) are ubiquitous in human populations. Three of these viruses have been discovered within the last 20 years. HHV-6 was first isolated from patients with a variety of lymphoproliferative and immunosuppressive disorders (Salahuddin et al. 1986), and exists in two closely related forms (Ablashi et al. 1993), one of which (HHV-6B) has been implicated as a causative agent of exanthem subitum (or roseola infantum), a common disease of infancy (Yamanishi et al. 1988). HHV-7 was first isolated from activated $CD4^+$ cells from a healthy person (Frenkel et al. 1990), and has also been implicated in exanthem subitum (Tanaka et al. 1994). HHV-8 was discovered by the detection of DNA sequences in Kaposi's sarcoma (KS) tissue from acquired immunodeficiency syndrome (AIDS) patients, but not in normal tissue (Chang et al. 1994). These sequences were subsequently detected in KS tissue from patients displaying the classic or endemic African forms of the disease and, often in association with Epstein–Barr virus (EBV), in AIDS-related primary effusion lymphomas. HHV-8 is now accepted as a causal agent of KS and, as a human tumor virus, is the subject of extensive research effort (Schulz 1998; Moore and Chang 2001a). Studies of HHV-8 counterparts in nonhuman primates have indicated that a ninth human herpesvirus species related to HHV-8 might exist (Schultz et al. 2000). To date, however, evidence has not been forthcoming.

Genome sequences for all known human herpesviruses are now available. Consequently, we know a great deal about how the genes are organized and what their functions are. Relating this type of information to general and particular aspects of herpesvirus pathogenesis presents an exciting challenge and has as an objective the control or prevention of infection.

Table 1 *Human herpesviruses*

Virus	Abbreviation	Genus	ICTV species name	G+C content (mol%)	Genome size (bp)
Herpes simplex virus type 1	HSV-1	α_1	Human herpesvirus 1	67	152 261
Herpes simplex virus type 2	HSV-2	α_1	Human herpesvirus 2	69	154 746
Varicella-zoster virus	VZV	α_2	Human herpesvirus 3	46	124 884
Epstein–Barr virus	EBV	γ_1	Human herpesvirus 4	60	171 823
Human cytomegalovirus	HCMV	β_1	Human herpesvirus 5	57	230 283[a]
Human herpesvirus 6[b]	HHV-6	β_2	Human herpesvirus 6	43	159 321 161 573 162 114
Human herpesvirus 7[b]	HHV-7	β_2	Human herpesvirus 7	40	144 861 153 080
Kaposi's sarcoma-associated herpesvirus[b]	HHV-8 (KSHV)	γ_2	Human herpesvirus 8	54	~140 500/801[c]

a) Laboratory strain (AD169; 229 354 bp) plus a 929 bp region deleted from a clone sequenced originally. Clinical isolates are approximately 5 kbp larger.
b) More than one strain has been sequenced.
c) Expressed as size of unique region/size of terminal repeat. Sequence at right end of unique region is unknown for the two sequenced isolates.

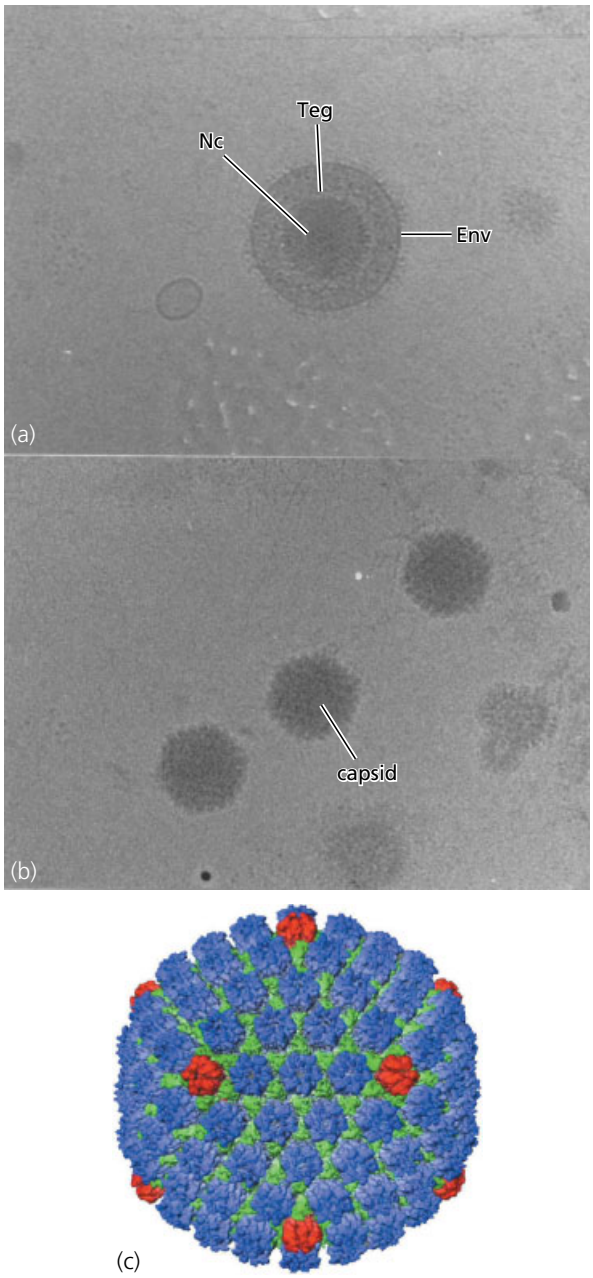

Figure 1 (a) *Electron cryomicrographs of* **(a)** *virions and* **(b)** *capsids of HSV-1. Visible in* **(a)** *are the capsid (Nc), tegument (Teg) and envelope (Env) with associated glycoprotein spikes (courtesy of Dr. F.J. Rixon);* **(c)** *three-dimensional reconstruction of the HSV-1 capsid surface structure. The view is along the two-fold axis. The hexons, pentons, and triplexes are shown in blue, red, and green, respectively (courtesy of Drs. H. Zhou and W. Chiu).*

MORPHOLOGY AND STRUCTURE

Morphology is the main factor in assigning viruses to the family *Herpesviridae*. Virions are comprised of four distinct structural elements: envelope, tegument, capsid, and core (Dargan 1986; Figure 1). The virion and capsid have diameters of 200–250 nm and 125 nm, respectively.

The lipid envelope is visible in negatively stained preparations as a pleomorphic structure with many short glycoprotein spikes. Contained within the envelope is the characteristic icosadeltahedral capsid, which in negatively stained preparations appears as an orderly array of stain-penetrated capsomers. Forming the icosahedron are 12 pentavalent capsomers at the vertices, 60 hexavalent capsomers at the 20 faces, and 90 hexavalent capsomers along the 30 edges – a total of 162 capsomers (Wildy et al. 1960). Electron-dense material is clearly present between the envelope and capsid, and the term 'tegument' has been used to describe this poorly understood region, which contains more than 20 viral proteins. Electron cryomicroscopy has been used to study frozen, hydrated herpesviruses, particularly capsids (Zhou et al. 2000). This approach allows direct examination of the three-dimensional structure without the use of stain or fixative. When combined with computer-assisted image enhancement, considerable surface detail is visible (Figure 1). Electron cryomicroscopic studies have also shown that the densely staining spherical core inside the capsid consists of the viral DNA packed at high density apparently without internal protein associations. Descriptions of toroidal structures detected in the core in earlier studies (e.g. Furlong et al. 1972) persist into the modern literature but are now accepted as artifacts of negative staining techniques.

REPLICATION

The replication cycle has been studied most fully with HSV-1, and this is the basis of the brief account given here. Fuller accounts of specific aspects of this subject are given in subsequent sections. An outline of the events that occur during HSV-1 replication is shown in Figure 2.

General aspects of the HSV-1 replication cycle are identical for HSV-2, but for other human herpesviruses less information is available, largely because of difficulties in propagating the viruses. No truly permissive cell culture system exists for EBV or HHV-8, and studies have been largely restricted to examination of latently infected cell lines. The diverse nature of human herpesviruses implies that details of their patterns of replication will vary. Nevertheless, replication cycles are all consistent with a sequential order of three major regulated phases of transcription and protein synthesis (Roizman and Knipe 2001).

The external glycoproteins of the virion have important roles in adsorption of virus to cells and subsequent penetration (Spear et al. 2000). Fusion of the virus envelope with the plasma membrane occurs at the cell surface rather than in internalized vesicles. Capsids are transferred to the nucleus via microtubules (Dohner et al. 2002), and viral DNA and at least some tegument proteins enter the nucleus, where transcription,

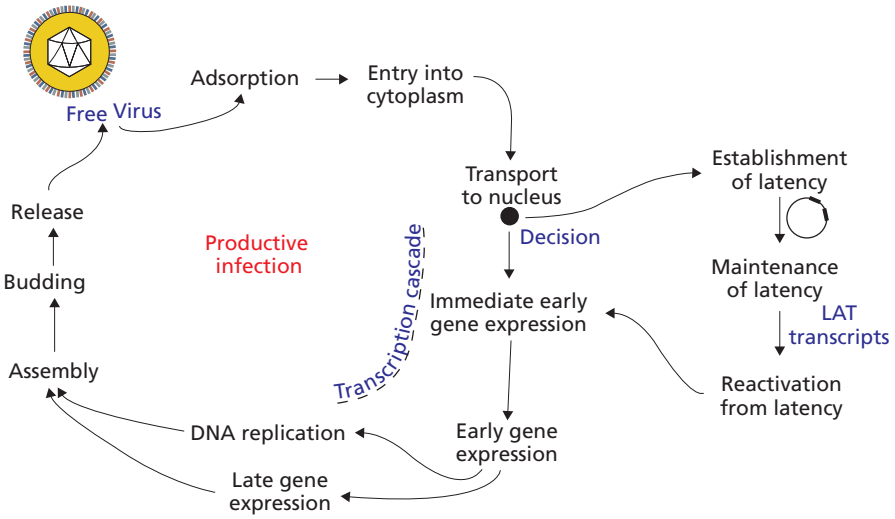

Figure 2 *The replication cycle of HSV-1*

replication of viral DNA and capsid assembly take place.

Viral DNA is transcribed into mRNA throughout infection by host RNA polymerase II, with various viral factors participating at all stages (Wagner 1985). Initially, a series of immediate–early (IE), or α genes is expressed whose transcription is independent of viral protein synthesis and is greatly enhanced by a tegument protein (O'Hare 1993). Certain IE proteins are *trans*-acting regulators of virus genes, and initiate a cascade of expression of early (or β) and late (or γ) genes (Honess and Roizman 1974). The products of early genes, defined as the subset expressed in the presence of functional IE products and before the onset of DNA replication, include several enzymes involved in DNA replication and nucleotide metabolism and a subset of glycoproteins. Late genes are dependent on functional IE proteins for expression, and in addition full levels of late protein synthesis require DNA replication. They encode mainly virion proteins. Small noncoding RNAs characteristic of γ-herpesvirus genomes are probably transcribed by RNA polymerase III.

A subset of viral genes is involved in DNA replication and packaging of DNA into capsids. DNA synthesis is initiated from one or more origins of DNA replication, generating head-to-tail concatemeric genomes apparently by a rolling circle mechanism (Boehmer and Lehman 1997). Concatemers are then cleaved and packaged into preformed capsids.

The process by which virion maturation occurs has long been controversial, but it is known that several genes are involved in directing envelopment and egress. The following scheme is probably correct (Elliott and O'Hare 1999; Skepper et al. 2001; Mettenleiter 2002). Capsids gain certain tegument proteins in the nucleus and then a membrane upon budding into the space between the two nuclear membranes. The membrane is lost on transit to the cytoplasm, where additional tegument proteins are added. Tegumented capsids then gain their envelope by budding into a component of the Golgi apparatus, or vesicles derived therefrom, and are released from the infected cell by reverse endocytosis.

The effects of these processes on host cells vary with the different viruses, and for an individual virus, depend on the cell type. The time taken for the cytopathic effect to become evident may range from hours to days, and cells may lyze, round up, or fuse. Also, the proportions of particles that are released from infected cells and the fraction that are enveloped are very variable.

Infection with HSV-1 leads to a rapid inhibition of host macromolecular synthesis. The initial phase of host shutoff is mediated by a virion component. Reduction of the functional half-lives of both infected cell and viral mRNAs by the virion shutoff component could promote rapid changes in viral gene expression in response to alterations at the level of transcription.

During infection, viral proteins interact with each other and with cellular proteins, and an increasing number of methods are available to detect such interactions. However, demonstrating physiological significance is often not straightforward and demands particular rigor. The great majority of studies of the replication cycle are carried out in vitro on infected tissue culture cells. Investigations of the replication cycle in vivo are revealing fresh insights and new gene functions. For example, analysis of the neural circuit-specific spread of α-herpesviruses (Enquist 2002). In addition to a lytic cycle of infection, all herpesviruses examined to date are able to undergo a latent cycle, discovering the molecular mechanisms of which presents further challenges to researchers (see Alphaherpesviruses: herpes simplex and varicella-zoster).

GENOME STRUCTURE

Types of structure

Herpesvirus genomes range in size from 125 to 245 kbp and nucleotide compositions from 32 to 74 percent G + C (Honess 1984). The γ-herpesviruses exhibit a global deficit in the 5′-CG dinucleotide, presumably as an evolutionary result of latency in dividing cells (Honess et al. 1989). The genome structures of many herpesviruses are known, but the majority of viruses in this family have not been examined at this level. Figure 3 illustrates the six types of genome arrangement that have been characterized thus far. A common characteristic is the presence of repeated regions at the ends of, or internally within, the genome. Similar genome structures have arisen independently during herpesvirus evolution, implying that this feature is not a reliable taxonomic tool in the absence of other data.

The simplest genome arrangement is that of group 1, which consists of a unique sequence flanked by a direct repeat. It was first described for channel catfish virus (CCV), and has since been found for equine herpesvirus 2 (EHV-2; γ_2-herpesvirus), and HHV-6. The genome of murine cytomegalovirus (MCMV; β_1-herpesvirus), also has this arrangement, but the direct repeats are much smaller.

Group 2 genomes contain a short sequence repeated a variable number of times at the termini instead of a single direct repeat, and are found among the γ_2-herpesviruses, such as HHV-8. The addition of a variable number of the terminal repeats in inverse orientation internally results in the group 3 genome structure, which has been described for cottontail rabbit herpesvirus, also a γ_2-herpesvirus. This genome exists in four equimolar isomers in virion DNA, since inversion of the two unique regions can occur by recombination between inverted repeats. The group 4 structure results from the presence of an internal set of direct repeats unrelated to the terminal set and is typified by EBV. The two unique regions do not invert in such a structure because of lack of homology between internal and terminal repeats.

In the group 5 structure, two unique regions (U_L and U_S) are each flanked by unrelated inverted repeats (TR_L/IR_L and TR_S/IR_S). The two orientations of U_S are present in equimolar amounts in virion DNA, but U_L is found predominantly or completely in a single orientation. Group 5 genomes are characteristic of α_2-herpesviruses, such as varicella zoster virus (VZV), but a separately evolved example is present in a fish herpesvirus, salmonid herpesvirus 1.

The group 6 structure is the most complex, although it was the first type to be described, for HSV-1 (Sheldrick and Berthelot 1974). It is similar to that of group 5, except that TR_L/IR_L is much larger, and the two orientations of U_L, as well as those of U_S, are present in equimolar amounts in virion DNA. HSV-2 and bovine herpesvirus 2, also an α_1-herpesvirus, and HCMV share this structure. Unlike group 5 genomes, group 6 genomes are terminally redundant, possessing a short sequence (termed the *a* sequence, some 400 bp in HSV-1) that is repeated directly at the genome termini and inversely at the IR_L–IR_S junction (Wagner and Summers 1978).

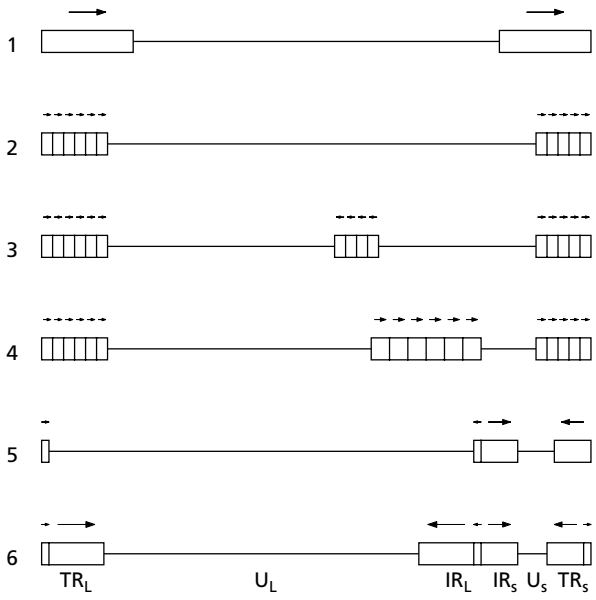

Figure 3 *Types of herpesvirus genome structure. The genomes are not drawn to scale. Unique and repeat regions are shown as horizontal lines and rectangles, respectively. The orientations of repeats are shown by arrows. The nomenclature used to designate regions of the HSV-1 genome are shown at the foot of the figure (from Davison and McGeoch 1995, courtesy of Cambridge University Press).*

Human herpesviruses

Figure 4 shows a scale representation of human herpesvirus genome structures. The HSV-1 and HSV-2 genomes exhibit a group 6 structure and are essentially colinear. Preparations of virion DNA from both viruses contain equivalent amounts of four isomers that differ in the relative orientations of U_L and U_S (Hayward et al. 1975), a phenomenon termed genome isomerization. These isomers appear to be functionally equivalent, and one has been chosen arbitrarily to serve as a prototype for depicting restriction endonuclease sites and the gene arrangement. As the *a* sequence contains signals for cleavage and packaging concatemeric DNA generated during viral DNA replication, the presence of internal copies as alternative sites, in combination with homologous recombination events between TR_L and IR_L or TR_S and IR_S, provides a means for generating the genome isomers.

The VZV genome, as an example of a group 5 structure, is not terminally redundant although sequences

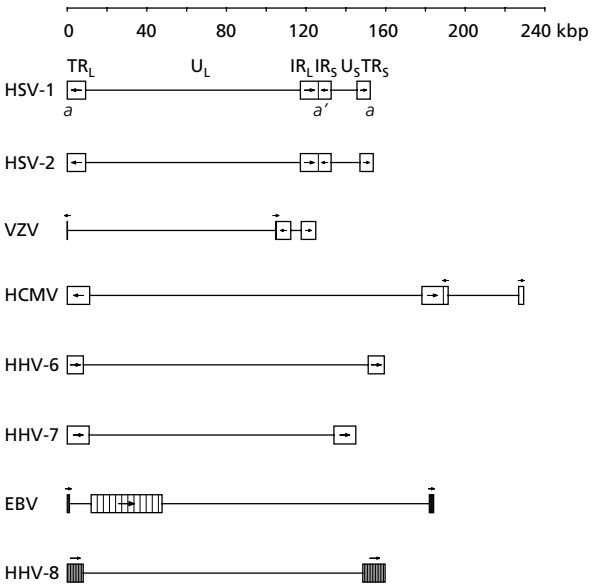

Figure 4 *Sizes and structures of human herpesvirus genome shown to scale. Unique and repeat regions are shown as horizontal lines and rectangles, respectively. The orientations of repeats are shown by arrows. The nomenclature used to designate regions of the HSV-1 genome is shown at the top of the figure. The sequence that is directly repeated at the genome termini and also present in inverse orientation is shown as* a *and* a′*, respectively.*

involved in cleavage and packaging of replicated DNA are present at the genome termini. U_L is flanked by a small inverted repeat of 88 bp that results in 5 percent of virions containing genomes with U_L inverted, and U_S is found equally in both orientations.

The general arrangement of the HCMV genome resembles that of HSV-1, with a similar arrangement of unique and repeated elements and the presence of four equimolar genome isomers, although it is 60 percent larger. TR_L/IR_L is much smaller in clinical isolates than in the sequenced laboratory strain (Prichard et al. 2001). Phylogenetic studies indicate that the genome structures of HSV-1 and HCMV developed independently. HHV-6 and HHV-7 are the only known β_2-herpesviruses. Although genetically related to HCMV, they share the distinct group 1 genome structure.

EBV DNA displays a linear, noninverting structure. The terminal regions consist of up to 12 copies of a tandem repeat (523 or 538 bp), and the internal repeat region comprises between six and 12 tandemly reiterated copies of a 3072 bp sequence. The HHV-8 genome is typical of that of γ_2-herpesviruses, consisting of a unique region flanked by a variable number of copies of an 801 bp terminal repeat.

In addition to large scale repeats, most human herpesvirus genomes contain several regions consisting of tandem reiterations of short sequence elements. The presence of the repeated elements in variable copy numbers results in genome size heterogeneity. These sequences may be coding or noncoding; in the former case, they exist as multiples of 3 bp and encode repeated amino acid sequences. A further type of genome heterogeneity is represented by the loss or gain of restriction endonuclease sites and is presumably due to differences in individual nucleotides. The DNA cleavage patterns of epidemiologically unrelated HSV-1 or HSV-2 isolates are not identical, and are stable when viruses are passed in cell culture. This characteristic has an important diagnostic use and has been employed to examine modes of transmission and epidemiology of HSV-1 and HSV-2 in human populations (Umene and Sakaoka 1999). Sequence data are being employed increasingly in studies of this type.

GENETIC CONTENT

Arrangement and expression

The complete (or almost complete) DNA sequences of 29 herpesviruses have been published to date, several for more than one strain. These are listed in Table 2. In addition, a substantial amount of data is available for parts of other herpesvirus genomes. Analyses of these sequences have given a detailed view of genetic content and usually form the starting point for experimental studies on particular genes.

The number of protein-coding genes estimated from sequence analyses ranges from about 70 in smaller genomes (e.g. HSV-1 and VZV) to over 160 in the larger (e.g. HCMV). In general, the great majority of the DNA is protein-coding, and genes are arranged about equally between the two strands. Regions of overlap between genes in different reading frames on the same strand or on opposing strands are infrequent and usually not extensive. Most genes are expressed as single exons from their own promoters, but it is common for families of genes arranged tandemly on the same strand to share a polyadenylation site downstream from the most 3′ member (Wagner 1985). Few α-herpesvirus genes specify spliced mRNAs, but splicing is more common in the β- and γ-herpesviruses. Most splicing in EBV specifically involves genes expressed during latency (Kieff and Rickinson 2001), particularly a family of genes distributed over 100 kbp that is expressed by differential splicing of transcripts from a common promoter. Complete transcript maps are not available for any herpesvirus, but transcriptome analyses have been derived from oligonucleotide microarray data for several, such as HSV-1 (Stingley et al. 2000). Microarray technology has also been used to investigate changes in cellular gene expression during infection with herpesviruses, such as HCMV (Zhu et al. 1998).

HSV-1

HSV-1 is the best characterized herpesvirus at the molecular level. The genome is considered to contain 74

Table 2 *Herpesvirus genome sequences*

Virus	Genome (bp)	GenBank accession	Primary reference
Alphaherpesvirinae			
Simplexvirus (α_1)			
Herpes simplex virus type 1	152261	X14112	McGeoch et al. (1988)
Herpes simplex virus type 2	154746	Z86099	Dolan et al. (1998)
Varicellovirus (α_2)			
Varicella-zoster virus	124884	X04370	Davison and Scott (1986)

a) See footnote (a) in Table 1.
b) Updated version of previous accession numbers.
c) Except for EHV-2, expressed as size of unique region/size of terminal repeat. Sequence at right end of unique region is unknown in the two HHV-8 isolates.

different genes, three of them present twice in the inverted repeats. The gene arrangement is shown in Figure 5. Data continue to accumulate on the properties and functions of the proteins encoded by these genes, and the current state of knowledge is summarized in Table 3. Several other potential protein-coding regions have been identified that overlap extensively with recognized genes, but their functional significance remains dubious (McGeoch and Davison 1999).

Overall, in excess of 85 percent of the DNA is protein-coding, and genes are tightly packed with about equal numbers oriented rightwards and leftwards. Several examples of two or more genes specifying mRNAs that share a 3′ terminus are visible in Figure 5. Larger mRNAs within these nested families contain more than one reading frame, and conventional wisdom suggests that translation initiates at the AUG codon proximal to the mRNA 5′ end. Owing to this nested arrangement, promoter sequences for certain internal mRNAs lie within the protein-coding sequences of overlapping mRNAs. HSV-1 has four genes that are expressed as spliced mRNAs, two (UL15 and RL2) with introns in protein-coding regions, and two (US1 and US12) with a common spliced 5′ noncoding leader in TR_S/IR_S. In addition, the HSV-1 latency-associated transcripts (LAT), which probably do not encode proteins, are also spliced. The LATs are the only transcripts expressed during latency (see Alphaherpesviruses: herpes simplex and varicella-zoster).

Presumably, all the genes present in a herpesvirus genome are required for natural growth and transmission of the virus. However, over half of the genes present in HSV-1 are 'nonessential', in that each of them may be removed individually without eliminating viral growth in cell culture (Roizman and Knipe 2001; see Table 3). Many of these mutants are attenuated when assayed in animal models.

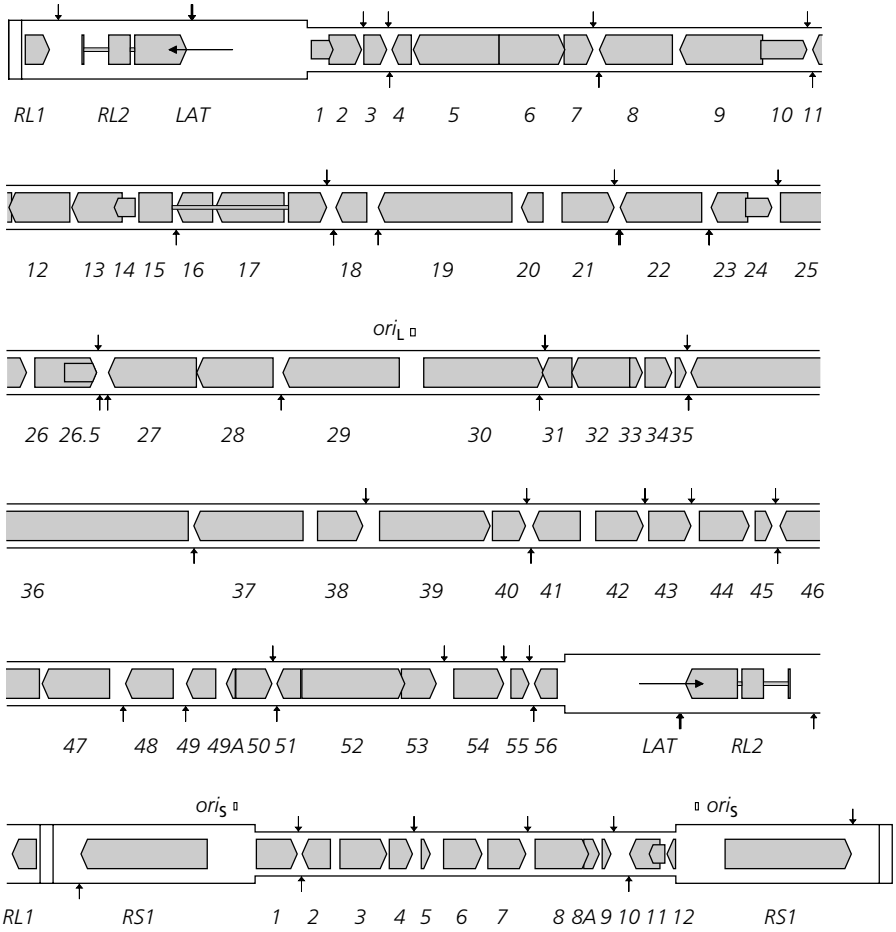

Figure 5 *Arrangement of genes in the HSV-1 genome. The genome is shown in six panels, each 25 kbp long. Inverted repeats are denoted by the thicker parts of the genome outline, and protein-coding regions are shown as shaded horizontal arrows. For the sake of clarity, the prefixes 'UL' (58 genes) and 'US' (13 genes) have been omitted from the gene nomenclature given below the genome; see Figure 4 for the locations of these regions. The major LAT RNA, presumed to be derived from a stable intron generated from a larger transcript, is also indicated by a horizontal arrow. Introns in genes* RL2 *and* UL15 *are shown as narrow bars; genes* US1 *and* US12 *are also spliced, but the intron is not shown because the 5′ exon is noncoding. Possible polyadenylation sites for mRNAs are indicated by vertical arrows above and below the genome for right and left oriented genes, respectively. The locations of* ori_s *and* ori_L *are shown by white rectangles above the genome (adapted from Davison (1992a), by courtesy of R&W Publications).*

Table 3 *Properties of HSV-1 proteins*

Gene	Predicted mass	Status	Function or properties
RL1	26194	NE	Neurovirulence factor (ICP34.5); inhibits host-controlled shutoff of protein synthesis
RL2	78452	NE	IE protein (ICP0; Vmw110); promiscuous transcriptional activator; role in ubiquitin-proteosome pathway
UL1	24932	E	Envelope glycoprotein L; complexes with glycoprotein H (UL22)
UL2	36326	NE	Uracil-DNA glycosylase
UL3	25607	NE	Nucleolar phosphoprotein
UL4	21516	NE	Nuclear protein
UL5	98710	E	Component of DNA helicase–primase complex; possesses helicase motifs
UL6	74087	E	Minor capsid protein; role in DNA packaging; putative portal protein
UL7	33057	NE	Tegument protein
UL8	79921	E	Component of DNA helicase-primase complex
UL9	94246	E	Binds to origins of DNA synthesis; possesses helicase motifs
UL10	51389	NE	Envelope glycoprotein M; disulfide-linked to UL49A protein
UL11	10486	NE	Myristylated tegument protein; role in virion envelopment
UL12	67503	(E)	Deoxyribonuclease; role in maturation/packaging of DNA
UL13	57193	NE	Tegument protein; probable serine-threonine protein kinase
UL14	23454	NE	Tegument protein; role in egress
UL15	80918	E	Role in DNA packaging; putative ATPase subunit of terminase; complexes with UL28 protein
UL16	40440	NE	Tegument protein
UL17	74577	E	Tegument protein; role in DNA packaging
UL18	34268	E	Capsid protein (VP23); component of intercapsomeric triplex
UL19	149075	E	Major capsid protein (VP5); forms hexons and pentons
UL20	24229	E/NE	Integral membrane protein; role in egress of nascent virions; host range phenotype
UL21	57638	NE	Tegument protein
UL22	90361	E	Envelope glycoprotein H; complexes with glycoprotein L (UL1); role in cell entry
UL23	40918	NE	Deoxypyrimidine kinase (dPyK or TK)
UL24	29474	NE	Nuclear protein
UL25	62664	E	Capsid-associated tegument protein
UL26	62466	E	Autocatalytically cleaved by N-terminal protease domain to give capsid protein (VP24) from N terminus and minor scaffold protein (VP21) of immature capsids
UL26.5	33758	(E)	Cleaved by UL26 protein to give major scaffold protein (VP22a) of immature capsids
UL27	100287	E	Envelope glycoprotein B; role in cell entry
UL28	85573	E	Role in DNA packaging; complexes with UL15 protein
UL29	128342	E	Single-stranded DNA-binding protein
UL30	136413	E	Catalytic subunit of replicative DNA polymerase; complexes with UL42 protein
UL31	33951	(E)	Nuclear matrix phosphoprotein involved in nuclear egress; complexes with UL34 protein
UL32	63946	E	Role in DNA packaging
UL33	14436	E	Role in DNA packaging
UL34	29788	(E)	Type II nuclear membrane protein involved in nuclear egress; complexes with UL31 protein
UL35	12095	NE	Capsid protein (VP26); located on tips of hexons
UL36	335841	E	Very large tegument protein
UL37	120549	E	Tegument protein
UL38	50260	E	Capsid protein (VP19C); component of intercapsomeric triplex
UL39	124043	E/NE	Ribonucleotide reductase large subunit (RR1)
UL40	38017	E/NE	Ribonucleotide reductase small subunit (RR2)
UL41	54914	NE	Tegument protein; virion host shutoff factor; RNase component
UL42	51156	E	Processivity subunit of replicative DNA polymerase; complexes with UL30 protein
UL43	44905	NE	Probable integral membrane protein
UL44	54995	NE	Envelope glycoprotein C; role in cell entry

(*Continued over*)

Table 3 *Properties of HSV-1 proteins (Continued)*

Gene	Predicted mass	Status	Function or properties
UL45	18178	NE	Type II membrane protein associated with envelope/tegument
UL46	78239	NE	Tegument protein; modulates IE gene transactivation VP16
UL47	73812	NE	Tegument protein; modulates IE gene transactivation by VP16
UL48	54342	E	Tegument protein (VP16; α-TIF; Vmw65); transactivates IE genes
UL49	32252	NE?	Tegument protein (VP22); capable of intercellular transport to uninfected cell nuclei; bundles microtubules
UL49A	9201	NE	Envelope protein disulfide-linked to glycoprotein M; glycosylated in some herpesviruses
UL50	39125	NE	Deoxyuridine triphosphatase (dUTPase)
UL51	25468	NE	Tegument protein
UL52	114416	E	Component of DNA helicase-primase complex
UL53	37570	(E)	Glycoprotein K; role in egress
UL54	55249	E	IE protein (ICP27; Vmw63); post-transcriptional regulator of gene expression
UL55	20491	NE	Nuclear protein
UL56	25319	NE	Membrane protein
RS1	132835	E	IE protein (ICP4; Vmw175); transcriptional regulator
US1	46521	E/NE	IE protein (ICP22; Vmw68); host range determinant
US2	32468	NE	Virion protein; interacts with cytokeratin 18
US3	52831	NE	Probably serine-threonine protein kinase; anti-apoptotic role; involved in nuclear egress
US4	25236	NE	Envelope glycoprotein G
US5	9555	NE	Envelope glycoprotein J; anti-apoptotic role
US6	43344	E	Envelope glycoprotein D; role in cell entry
US7	41366	NE	Envelope glycoprotein I; complexed with glycoprotein E in Fc receptor
US8	59090	NE	Envelope glycoprotein E; complexed with glycoprotein I in Fc receptor
US8A	16801	NE	Nucleolar phosphoprotein
US9	10026	NE	Type II membrane protein associated with envelope/tegument; role in axonal localization of viral membrane proteins
US10	34053	NE	Tegument protein
US11	17756	NE	Virion protein; double-stranded RNA-binding protein; prevents cellular PKR activation
US12	9792	NE	IE protein (ICP47; Vmw12); interferes with maturation of MHC class I molecules

Developed from Davison and Scott (1986), McGeoch et al. (1988), (1993), McGeoch (1989), McGeoch and Schaffer (1993), Davison (1993), Ward and Roizman (1994), and Davison (2000).
Genes in bold type are thought to have been inherited from the ancestor of the α-, β-, and γ-herpesviruses, and all but *UL9*, *UL23*, and *UL40* are conserved in each subfamily. The status of each gene in cell culture is indicated: E, essential; NE, non-essential; NE?, probably essential; (E), a mutant is viable, but very disabled; E/NE, non-essential under certain conditions.

Other herpesviruses

Comparisons of amino acid sequences predicted from DNA sequence data have shown that, despite substantial differences in nucleotide composition or genome structure, members of the same subfamily share the great majority of genes in a very similar layout. For example, all but six VZV genes have counterparts at equivalent locations in the HSV-1 genome. The utility of comparing a less well understood genome (e.g. VZV) with a better characterized one (HSV-1) depends on this genetic correspondence. When viruses in the three subfamilies are compared, however, divergence is much greater, with a set of 'core' genes conserved in blocks that have been rearranged during evolution. These genes number 43 and were inherited from the common ancestor of the α-, β-, and γ-herpesviruses. They are indicated in bold type in Table 3, and presumably function in processes that are central to growth and survival. Three core genes are found in only two of the three subfamilies, and this probably reflects genetic loss from one lineage. Genes encoding thymidine kinase and the small subunit of ribonucleotide reductase, for example, are not present in the β-herpesviruses. The 'noncore' genes are characteristic of each subfamily, and some are unique to one or a few very closely related viruses. Many are involved in aspects of pathogenesis that contribute to survival of the virus in its particular ecological niche. Most genes involved in control processes and latency also fall into this category.

Herpesvirus evolution

Analyses of the genetic relationships between α-, β-, and γ-herpesviruses implies that they have evolved from a common ancestor by processes including substitution, deletion, and insertion of nucleotides to modify genes or produce genes de novo and recombination processes resulting in gene duplication and divergence, capture of host genes, and gene rearrangement (McGeoch and Davison 1999). The results of phylogenetic studies (McGeoch et al. 1995, 2000) are in general accord with the notion that herpesviruses have generally (but not universally) coevolved with their hosts, and this has allowed a timescale to be proposed for the evolution of mammalian herpesviruses (Figure 6). These studies provide a firm basis for herpesvirus classification based on genetic relationships rather than on phenotypic properties.

Herpesviruses of birds and reptiles are similar to those of mammals, grouping with the α-herpesviruses. The family also contains two other major clades: fish and amphibian herpesviruses, and invertebrate herpesviruses (McGeoch and Davison 1999). The fish herpesviruses, exemplified by CCV, are only marginally related to herpesviruses that infect mammals or birds (Davison 1992b). However, evidence relating to capsid structure and assembly indicates that these herpesviruses share a common ancestor presumably dating from the time when the lineages leading to fish and other vertebrates separated (approximately 400 million years ago). The two viral lineages seem to have diverged so far that their shared inheritance is no longer discernible by amino acid sequence comparisons. The single known herpesvirus of an invertebrate, which infects several bivalve species including oysters, is very tenuously related to both fish and mammalian herpesviruses. The common ancestor of modern invertebrate and vertebrate herpesviruses is proposed as having existed about a billion years ago.

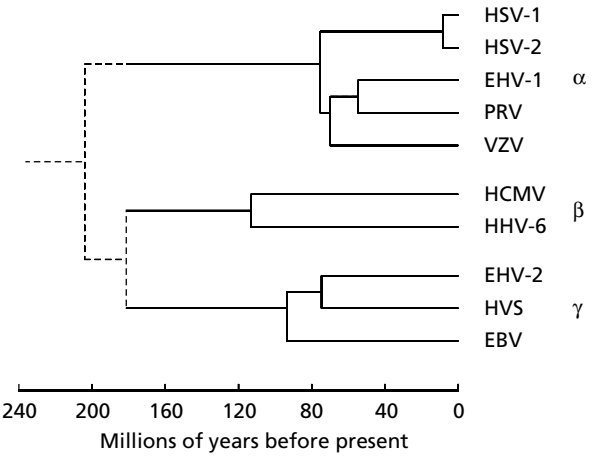

Figure 6 *A phylogenetic tree for the herpesviruses derived from sequence comparisons, with a time-scale based on the hypothesis that viruses cospeciate with their hosts. Broken lines indicate regions of lower confidence. PRV, pseudorabies virus (from McGeoch et al. 1995, with permission from Elsevier).*

GENE FUNCTION

Determination of function

Computer-aided comparisons of predicted amino acid sequences have facilitated the identification of some herpesvirus gene functions, but the majority of evidence has come from direct genetic and biochemical experimentation based on sequence information. Most information has been gained for HSV-1, and derived functions of core genes have been imputed to homologous genes in other herpesviruses. Considerable progress has also been made with noncore genes, including those of HCMV, EBV, and HHV-8. The major categories of gene functions are described below.

Control

Some proteins are involved in control processes, the most intensively studied acting directly or indirectly at the level of transcription to regulate gene expression during the infectious cycle. One such, the HSV-1 virion transactivator (Campbell et al. 1984), an essential structural component of the tegument termed VP16 (Vmw65 or α-TIF; gene *UL48*), acts to stimulate selective transcription of IE genes. Although the transactivation function of VP16 is not essential for virus growth, mutants in the appropriate domain initiate replication inefficiently at low multiplicities of infection and are avirulent in some animal model systems. Induction of HSV-1 IE genes may determine aspects of cell tropism and could play a role in reactivation from latency. Transactivation by a related protein may also occur in other α-herpesviruses, but it is not clear that the mechanism is the same. An unrelated virion protein transactivates HCMV promoters (Liu and Stinski 1992).

Coordinate induction of HSV-1 IE genes requires a consensus DNA signal (TAATGARAT) that is well conserved upstream of all five IE genes. This positive regulation of IE transcription acts through the cellular Oct-1 DNA-binding protein, and studies of VP16 function have shed light on the assembly of multicomponent transcriptional complexes (O'Hare 1993). Four IE proteins are involved in regulation of early and late virus genes (Everett 1987). Two, ICP4 (Vmw175; gene *RS1*) and ICP27 (Vmw63; gene *UL54*) are essential for replication, but precisely how these two proteins function remains obscure. ICP4 is required throughout productive infection (Watson and Clements 1980), and acts at the transcriptional level exhibiting nonspecific DNA-binding. ICP27 is a multifunctional protein that regulates transcriptional and post-transcriptional processes (Phelan

and Clements 1998). Among its post-transcriptional effects are inhibition of splicing of viral and cellular transcripts and promotion of nuclear export of viral RNAs (Koffa et al. 2001). ICP0 (Vmw110; gene *RL2*) is not absolutely required for HSV-1 replication, but is required for reactivation from latency. It has a role in overcoming suppression of viral genomes by degrading a number of cellular proteins via the ubiquitin-proteosome pathway (Everett 2000), and acts as a ubiquitin ligase in vitro (Boutell et al. 2002). Mutants of ICP22 (Vmw68; gene *US1*) are viable, but affected in host range in cell culture. The functions of this protein are not yet understood.

Considerable information is available on regulation of β-herpesvirus gene expression, largely from HCMV studies, particularly on gene functions that promote the regulated cascade of gene expression and on the viral *cis*-acting DNA sequences involved (Mocarski and Tan Courcelle 2001). Similarly, EBV and HHV-8 have been well studied both in terms of gene expression during latent infection of B-lymphocytes, and of lytic gene expression occurring following treatment of latently infected cell lines with various inducers (Kieff and Rickinson 2001; Moore and Chang 2001b).

These studies have shown that all herpesviruses examined encode strong transcriptional regulators that are expressed in the IE replication phase. However, the relevant genes appear to have developed separately in the herpesvirus lineages. This diversity is also shown by the DNA sequences that regulate synthesis of these proteins. Perhaps a similarity in tertiary structure enables these proteins to act in similar ways; alternatively, they may exert their effects by interaction with different host cell factors.

Other virus proteins modulate replicative processes in the infected cell. Amongst the α-herpesviruses, two protein kinases (encoded by genes *UL13* and *US3*, the former conserved in β- and γ-herpesviruses) are likely to act in this way. Numerous viral and cellular targets have been identified, but their physiological relevance, and hence the true roles of the enzymes, remain to be identified. The virion host shutoff function encoded by gene *UL41* is a component of an RNase that reduces the cytoplasmic stability of both cellular and viral mRNAs and serves to switch off synthesis of host cell proteins (Lu et al. 2001). This activity may also contribute to the downregulation of early viral gene expression. Viruses in each subfamily also have sophisticated genetic mechanisms for suppressing the host's immune response.

Nucleotide metabolism

Herpesviruses specify several enzymes involved in nucleotide metabolism or DNA repair (Morrison 1991). It is likely that the genes encoding these enzymes were captured at various times from the cell. Virus-specified enzyme activities generally have biochemical properties that differ from their cellular counterparts, and this is an important feature for specific targeting of certain antiviral compounds (Coen 1992).

Two HSV-1 enzymes catalyze reactions in the biosynthesis of DNA precursors: thymidine kinase (TK) and ribonucleotide reductase (RR). HSV-1 TK (gene *UL23*) appears to be evolutionarily derived from cellular deoxyribonucleoside kinase, which is known in humans as mitochondrial thymidine kinase 2 (Johansson et al. 1999). In being able to phosphorylate thymidine and deoxycytidine, the viral enzyme is more accurately described as a deoxypyrimidine kinase. HSV-1 TK activity is important for the inhibitory action of nucleoside analogs, such as acyclovir, which are phosphorylated to their monophosphate forms by the viral enzyme and subsequently to the di- and tri-phosphate forms by cellular enzymes. HSV-1 TK is not essential for viral replication in actively growing cells, but is required for growth in resting cells. The pathogenicity of TK-deficient viruses is reduced in animal models, presumably because TK activity is required to raise dTTP levels in targeting nondividing cells. As might be expected, the enzymatic properties of TK enzymes specified by different herpesviruses differ, for example in their relative ability to phosphorylate thymidine and deoxycytidine. The TK gene is not ubiquitous: the α- and γ-herpesviruses (and even CCV) contain TK genes, but the β-herpesviruses such as HCMV and HHV-6, do not, presumably because of gene loss in that lineage.

RR catalyzes the reduction of nucleoside diphosphates to deoxynucleoside diphosphates, and comprises a large (RR1) and a small (RR2) subunit encoded by genes *UL39* and *UL40*, respectively (Connor et al. 1994). It occupies a central role in metabolic routes for the supply of DNA precursors, and is required for efficient growth of virus in cell culture. RR-deficient viruses grow slowly and are nonpathogenic. Kinetic experiments have shown that RR2 is one of the earliest HSV-1 gene functions to be expressed. The genes encoding both subunits of RR are present in α- and γ-herpesvirus genomes. However, only RR1 is encoded by β-herpesviruses, and the absence of active site residues indicates that it is probably inactive. CCV lacks both genes. Interest has focused on the intersubunit interaction as a target for antiviral compounds, and this in turn has turned attention on essential interactions between other herpesvirus proteins, such as those involved in DNA replication, capsid assembly and DNA packaging (Marsden 1992).

HSV-1 encodes a deoxyuridine triphosphatase (dUTPase; gene *UL50*), which is not essential for growth in cell culture. This enzyme catalyses conversion of dUTP to dUMP, which can then be methylated to dTMP by cellular thymidylate synthase. The important function of viral dUTPase in infected cells, however, may be to reduce misincorporation of uracil during

DNA synthesis. A dUTPase gene is present in all herpesviruses studied to date, and appears to have developed in the α-, β-, and γ-herpesviruses by capture of the gene, followed by gene duplication and fusion of the two protein-coding regions. An analysis of conserved motifs casts strong doubt, however, on whether the β-herpesvirus gene is a functional dUTPase.

HSV-1 gene *UL2* encodes a uracil-DNA glycosylase, which is likely to function in removing spontaneously deaminated cytosine and misincorporated uracil residues from viral DNA and thus reduce mutations. This gene is highly conserved in the α-, β-, and γ-herpesviruses (not CCV), but is not essential for growth of HSV-1 in cell culture.

Other enzymes with roles or potential roles in nucleotide supply have been characterized in certain herpesviruses. Thymidylate synthase (TS), which catalyzes methylation of dUMP to dTMP, is encoded by VZV and certain γ_2-herpesviruses, such as HHV-8. Dihydrofolate reductase, which catalyses reduction of dihydrofolate to tetrahydrofolate, an essential step in purine synthesis and in the action of TS, is also specified by certain γ_2-herpesviruses. γ-Herpesviruses contain one or more copies of genes derived from cellular phosphoribosylformylglycinamidine synthase, which is involved in purine biosythesis. CCV possesses duplicated deoxynucleoside monophosphate kinase genes apparently captured from a bacteriophage.

DNA replication

Seven HSV-1 proteins constitute essential components of the DNA synthesis machinery, including a replicative DNA polymerase comprising two subunits, a single-stranded DNA-binding protein, three constituents of a helicase–primase complex and a protein that recognizes the origins of viral DNA replication (Challberg 1991). There has been significant progress in understanding the roles of these proteins, and several interactions in the replication complex have been characterized (Stow 2000). The possible involvement of cellular proteins, however, has not been investigated in any detail, and no origin-dependent in vitro DNA replication system has been developed. The replicative machinery of α-, β-, and γ-herpesviruses is in broad outline the same, since counterparts of six of the seven proteins are present in all mammalian herpesviruses. However, each subfamily utilizes a different means of directing the replication complex to viral DNA, and this is reflected in the lack of conservation of the α-herpesvirus origin-binding protein in the other subfamilies (except the β_2-herpesviruses) and the observation that each subfamily uses a different type of origin of replication. These differences have presumably arisen as a result of evolutionary pressures exerted on each virus during the lytic and latent cycles of infection.

HSV-1 has an origin of replication (ori_S) which, being located in TR_S/IR_S, is present in two copies in the genome (Figure 5). In addition, a related origin (ori_L) is located near the center of U_L. Other α-herpesviruses also possess ori_S at an equivalent location. Most have ori_L, in some cases at a different location in U_L, but VZV lacks this origin of replication. Both copies of ori_S or the single copy of ori_L may be deleted from the HSV-1 genome without affecting viability. Ori_S and ori_L are related in sequence and consist of an AT-rich palindrome flanked by short sequences that are recognized by the origin-binding protein, and both probably function during lytic replication. EBV also has two unrelated origins of DNA replication but, in contrast to HSV-1, these function at different stages of the life cycle (Hammerschmidt and Mankertz 1991). Ori_P is required for maintaining genome copy number in dividing cells, and is recognized by an EBV-encoded protein, EBNA-1. Ori_{Lyt}, which is required for lytic amplification of EBV genomes, consists of a much more extended region than HSV-1 ori_S or ori_L, and contains several important sequence elements. Ori_{Lyt} has also been identified in the HCMV and HHV-8 genomes (Hamzeh et al. 1990; AuCoin et al. 2002), and ori_P in the HHV-8 genome (Garber et al. 2001).

DNA polymerase has been well characterized at the genetic and biochemical levels. The catalytic subunit (gene *UL30*) is the target of antiviral agents, such as phosphonoformic and phosphonoacetic acids, which mimic dNTPs, and is the site of genetic resistance to such compounds. The associated, smaller subunit of DNA polymerase (gene *UL42*) increases the processivity of the holoenzyme. Two of the components of the helicase-primase complex (genes *UL5* and *UL52*) are essential for both enzyme activities; the UL5 protein contains a helicase domain. The third component (gene *UL8*) has an auxiliary function, and also interacts with the origin-binding protein. The origin-binding protein (UL9) consists of a homodimer, with each subunit comprising a domain that binds to the origin of replication and a helicase domain that may function in unwinding the origin to allow access to the replication complex. The single-stranded DNA-binding protein (gene *UL29*) also interacts with the origin-binding protein.

DNA packaging

The events that occur during packaging of viral DNA into immature capsids are not well understood. As with capsid assembly, this area attracts interest because of the possibility of antiviral intervention in essential herpesvirus-specific processes. Indeed, it is encouraging that one class of compound (benzimidazole ribonucleosides) has been shown to inhibit the machinery involved in DNA packaging (Underwood et al. 1998).

Eight HSV-1 genes have thus far been identified from their phenotypic effects on mutant viruses as having roles in DNA packaging (*UL6*, *UL12*, *UL15*, *UL17*, *UL25*, *UL28*, *UL32*, and *UL33*). It is unlikely that the products of these genes are all central to the packaging mechanism. The UL6, UL25, and UL17 proteins are virion components. The UL6 protein is exclusively part of the capsid and is thought to form the portal for entry of DNA (Newcomb et al. 2001). At least a proportion of the UL25 protein is capsid-associated, and the UL17 protein is in the tegument. The UL15 protein is of interest because it bears sequence similarity to ATPases and to the large subunit of the bacteriophage T4 terminase, which is responsible for energy-driven insertion of DNA into the capsid. This observation suggests that some aspects of HSV-1 DNA packaging might find parallels in bacteriophage T4, and supports the speculative view that herpesviruses and T4 may share a common, but very ancient, evolutionary origin. The *UL15* gene is unusual in that has highly conserved counterparts in all herpesviruses and is expressed as a spliced mRNA in the vertebrate viruses. The UL15 protein interacts with the UL28 protein. UL12 encodes an alkaline exonuclease, which may be responsible for resolving DNA structures produced during replication.

Virion structure

DEGREE OF COMPLEXITY

About half of the total number of HSV-1 genes specify components of the viral particle. These proteins include eight capsid constituents, at least 20 tegument components, and more than ten proteins, most glycosylated, in the envelope. The proteins making up the capsid are better characterized than those in the envelope or tegument. Capsid proteins can be envisaged as providing a robust, self-assembling container for the viral genome, tegument proteins as ancillary factors responsible for enhancing viral infection, and envelope proteins as molecules involved in allowing infecting virions to enter cells efficiently and facilitating mature virions to exit the infected cell.

CAPSID

The proteins that make up HSV-1 capsids are conserved in other herpesviruses, and the capsid structures of widely diverged members (such as HSV-1 and CCV) are similar. Thus, it is likely that the same basic mechanism for capsid maturation is fundamental to all herpesviruses. The proteins that make up the HSV-1 capsid have undergone extensive characterization (Homa and Brown 1997), and the structure of the capsid has been analyzed in some detail by electron cryomicroscopy. A single protein, VP5 (gene *UL19*), makes up the hexameric and pentameric capsomers of the HSV-1 capsid, and the intercapsomeric regions are composed of a complex (known as a triplex) of two copies of VP23 (gene *UL18*) plus a single copy of VP19C (gene *UL38*). The external tips of hexameric capsomers are decorated with a small protein, VP26 (gene *UL35*). The capsid also contains a protease, VP24 (gene *UL26*). The protein encoded by gene *UL6* is present in a small number of copies per capsid.

The steps that occur during capsid formation are reminiscent of those that take place during maturation of certain DNA-containing bacteriophages, such as T4, in that replicated DNA enters preformed immature capsids containing a core of scaffolding proteins, which are expelled in a process involving specific proteolytic events. The HSV-1 scaffold proteins are encoded by the overlapping genes *UL26* and *UL26.5* (Liu and Roizman 1991; Figure 5). The UL26.5 protein is identical to the C-terminal portion of the UL26 protein. Proteolytic action of the N-terminal domain of the UL26 protein on the UL26 protein itself at two locations, one central and one near the C terminus, and on the UL26.5 protein at the site near the C terminus generates VP24 (the protease) and VP21 (the minor scaffold protein) from the UL26 protein, and VP22a (the major scaffold protein) from the UL26.5 protein. During DNA packaging, VP21 and VP22a are expelled from the capsid interior, but VP24 is retained.

The molecular events that occur during capsid maturation have been unraveled with the aid of a system in which the HSV-1 proteins are expressed from baculovirus recombinants (Thomsen et al. 1994; Tatman et al. 1994), and, more recently, with purified proteins (Newcomb et al. 1999). VP5, VP23, VP19C are essential for capsid assembly, plus either the gene UL26.5 protein which gives rise to VP22a or, at a reduced efficiency, the gene UL26 protein which gives rise to VP21 and VP24. The proteolytic function of the UL26 protein is thus not essential in this system, but its requirement for virus production during HSV-1 infection indicates that it is involved in removal of the scaffold proteins during DNA packaging. It appears that the immediate product of capsid assembly is a spherical 'procapsid' which angularizes to a capsid during DNA packaging (Trus et al. 1996).

TEGUMENT

The tegument has a complex composition, and demonstrates icosahedral structure only in the region immediately adjacent to the capsid surface (Chen et al. 1999). It is a feature of all members of the family but, in contrast to capsid proteins, most components of the tegument are specific to a particular subfamily or genus and are therefore likely to have important roles in modulating the virus–host interaction, rather than as passive structural components of the virion. Examples of such roles for HSV-1 tegument proteins are the virion host shutoff

factor (gene *UL41*), VP16 (gene *UL48*) and the UL13 protein kinase. It is likely that additional functions for tegument proteins will emerge as this area of research develops.

ENVELOPE

At least 11 HSV-1 genes encode membrane-associated glycoproteins, and most of these are present in the virion envelope. The glycoproteins are located in membranes by virtue of one or several hydrophobic domains, and thus are exposed on the exterior of infected cells or virions. Also, some are functionally associated with initial virus–host interactions (Shukla and Spear 2001) and are therefore likely to be of considerable importance for pathogenicity. For this reason, and because of their utility in vaccine development, herpesvirus glycoproteins have been the subject of intense scrutiny.

Many glycoproteins are specific to genera or subfamilies. For example, three HSV-1 glycoproteins lack counterparts in VZV (gD, gG, gJ). Only gB, gH, gL, gM, and gN (which is not glycosylated in some herpesviruses, including HSV-1) have counterparts across the α-, β-, and γ-herpesviruses. HCMV contains extensive families of related glycoprotein genes that appear to have been generated by gene duplication and divergence (Chee et al. 1990), and thus represent a striking evolutionary experiment in generating genetic diversity.

The initial interaction of HSV-1 with cells involves the binding of gC or gB to heparan sulfate proteoglycans present on the cell surface (Spear et al. 2000). gD then binds to one of several receptors in the TNF-receptor family or immunoglobulin superfamily or to specific forms of heparan sulfate. The viral and cellular membranes fuse in a process that requires gB, gD, gH, gL, and the gD receptor, and the capsid and tegument are released into the cytoplasm. Like HSV, HCMV uses heparan sulfate as a cell surface receptor for the initial binding of virus. EBV, however, binds to cells in a different manner. The EBV virion glycoprotein gp350/220, which lacks sequence counterparts in the α- and β-herpesviruses, binds the cellular receptor CD21 that is found on B-lymphocytes (Kieff and Rickinson 2001). The nature of the receptor for EBV on epithelial cells remains unresolved. HHV-8 appears to enter cells via heparan sulfate and an integrin receptor (Akula et al. 2002).

Of the HSV-1 glycoproteins that are not required for growth of virus in cell culture, three interact with key elements of the immune system: gC binds to the C3b component of the complement system and gE and gI form a complex that can bind the Fc constant region of immunoglobulin G. Of the essential glycoproteins, gH and gL associate during maturation in endoplasmic reticulum and are present as a heterodimer in virions. Also, gM is disulfide-linked to gN. HSV-1 is unusual in that gB in other herpesviruses is processed by a trypsin-like cleavage into a disulfide-linked dimer.

Pathogenesis

Some viral proteins have specific roles in disease processes, including latency. These proteins help to fit a virus to an ecological niche and are usually specific to a subfamily or genus. They may have little effect on the growth of virus in cell culture, but may profoundly influence virus virulence in vivo. Functional analyses of such genes are fundamental to our understanding of herpesviruses as infectious agents. This information is crucial for the design of safe and effective herpesvirus vectors for gene replacement and tumor therapy and for the development of live vaccines. The mechanisms used by herpesviruses to control the processes of natural infection are steadily being elucidated, and the knowledge gained is likely to lead to novel therapies. Herpesviruses are seen increasingly as sophisticated manipulators of various cellular mechanisms and defenses in sophisticated ways, including the cell cycle, apoptosis and various aspects of the immune response (Roizman and Knipe 2001; Hengel et al. 1998).

Herpesvirus genes that modulate the immune response appear to be more numerous in the β- and γ-herpesviruses (Johnson and Hill 1998; Reddehase 2000; Neipel et al. 1997). Among the α-herpesviruses, in addition to gC, gE, and gI which can interact with the immune system, a gene specific to HSV-1 and HSV-2 (gene *US12*) encodes an IE protein (ICP47 or Vmw12) which interferes with maturation of MHC class I proteins in infected cells by interacting with the TAP peptide transporter complex (York et al. 1994). The product of gene *RL1* (ICP34.5) is specific to HSV-1 and HSV-2 and related to proteins implicated in cell differentiation, and has a profound effect on neuropathogenicity (Chou et al. 1990). It appears to function by promoting dephosphorylation of eIF-2α and thereby inhibits host-controlled shutoff of protein synthesis (He et al. 1997). RL1 null mutant viruses are not neurovirulent in vivo, and exhibit limited replication at peripheral sites, but fail to replicate in neurons of the peripheral nervous system. These viruses can, however, establish latent infections from which they can be reactivated. RL1 mutants are currently being evaluated for their possible utility in human tumor therapy (Markert et al. 2001).

Alphaherpesviruses: herpes simplex and varicella-zoster

ANTHONY C. MINSON

Herpes simplex virus 1
Varicella-zoster virus 7
References 12

Herpes simplex virus (HSV) types 1 and 2 (HSV-1 and HSV-2) and varicella-zoster virus (VZV) are alpha herpesviruses that are related in their genetic and biological properties. Their genomes are composed of homologous sets of genes organized in a co-linear fashion; they cause productive cytolytic infection of epithelial cells, and establish life-long latent infections in sensory nerve ganglia. There are, however, important biological differences:

- VZV infection has a viremic phase whereas HSV infectivity is usually limited to the epithelium and sensory nerves at the infection site
- HSV is transmitted only by contact whereas VZV is airborne and contagious
- VZV is highly species-specific whereas HSV can infect, experimentally, a wide range of species.

Indeed, our knowledge of HSV pathogenesis and immunity derives largely from studies of the virus in rodents. HSV-1 and HSV-2 are closely related: they crossreact antigenically, exhibit extensive nucleotide sequence homology and their genes are functionally homologous because stable intertypic recombinants can be generated readily in tissue culture. However, despite the fact that HSV-1 and HSV-2 can infect similar sites in humans, recombination between these viruses does not appear to occur in vivo, and genetic comparison suggests that the two subtypes have evolved independently for more than 5 million years (McGeoch and Cook 1994).

HERPES SIMPLEX VIRUS

Clinical manifestations

HSV infects mucosal epithelium or damaged cutaneous epithelium, and infection can therefore occur at a variety of sites, but oral and genital infections are most common. HSV-2 is predominantly responsible for genital infection but HSV-1 contributes significantly, representing 30–50 percent of genital isolates in some studies (Buckmaster et al. 1984; Ross et al. 1993). By contrast, HSV-2 is rarely isolated from oral lesions. The basis of this preference for different mucosal surfaces by the two virus types is unknown but the predominance of HSV-2 'below the waist' and HSV-1 'above the waist' extends to other sites. Thus anal lesions, cutaneous lesions of the thighs and buttocks, and infections of the neonate during birth are more frequently caused by HSV-2 whilst eye infections and cutaneous lesions of the head and neck are usually caused by HSV-1. Regardless of the site of infection or the virus type, HSV enters sensory nerve endings during primary infection and is transported to the neuronal cell body where latent infection is established. Since oral and genital infections are by far the most common, the trigeminal and sacral ganglia are the usual sites of latent infection by HSV-1 and HSV-2, respectively. The majority of the adult population is latently infected with HSV, but it is clear that infection rates greatly exceed clinical disease rates and many, perhaps most, individuals who are latently

infected with HSV have no recollection of primary infection and do not suffer recurrent lesions.

Primary oral infection presents as an acute gingivostomatitis comprising painful ulcers in the mouth, which resolve within a few weeks, often accompanied by fever and enlargement of local lymph nodes. A significant proportion of sore throats is also thought to be caused by primary oral HSV, and this may be the most common manifestation of primary infection. During the course of primary infection the virus establishes a lifelong latent infection in neurons of the trigeminal ganglia, and 'reactivation' results in the reseeding of virus into the oral epithelium and shedding in saliva. A minority of seropositive people suffer periodic clinical recurrences, the classic 'cold sores,' crops of vesicles on the mucocutaneous junctions of the mouth and nose which ulcerate, crust, and heal within 4–7 days (Figure 1). Some of these individuals recognize a prodromal tingling or burning sensation which heralds the development of the recurrent lesion. Recurrences are provoked by a variety of stimuli, including sunlight, physical trauma, stress, respiratory infections, and hormonal change, but it is not known whether these stimuli act by a common pathway. The development of a cold sore requires reactivation of the latent virus in the ganglia followed by the establishment of a focus of epithelial infection; a provoking stimulus might operate either by triggering a reactivation in the ganglia or by modifying the susceptibility of the relevant epithelium such that a ganglionic reactivation, which would otherwise have been silent, results in a clinical recurrence.

Genital herpes consists of painful vesicles on the genitalia or anal region. Aseptic meningitis has been reported as a complication of primary infection, and proctitis has been reported in homosexual men. HSV-2 appears to be almost exclusively responsible for these complications. As with oral infection, many primary genital infections are inapparent and the first indication of infection may be a recurrence, an episode that has been termed 'initial infection' to distinguish it from the primary infection (Corey et al. 1983). Genital herpes infections recur at a higher frequency than oral infections, and genital HSV-2 infections recur more frequently than genital HSV-1 infections (Lafferty et al. 1987). The frequency and severity of recurrent episodes usually decrease with time but recurrent genital herpes is a painful and distressing disease, and many patients suffer frequent recurrences for many years. Reactivation of latent virus and shedding in genital secretions occur at a much higher rate than clinical disease.

Figure 1 *Vesicular cold sores due to recurrent herpes simplex. (Photograph courtesy of Dr. Jane Sterling, Addenbrooke's Hospital, Cambridge, UK: Copyright Addenbrooke's NHS Trust.)*

Infection of the skin, manifest as a crop of classic herpetic vesicles, can occur on any part of the body, most commonly the head or neck, and probably always results from the contamination of damaged skin by virus in saliva or genital secretions. Infection may result from intimacy or activities likely to cause abrasion, such as wrestling (herpes gladiatorum) or rugby (scrum pox). Lesions on the fingers (herpetic whitlows) are an occupational hazard for healthcare workers. A particularly severe disease results from infection of eczematous skin (eczema herpeticum), in which the virus spreads widely, causing large areas of ulceration.

Herpes infections of the eye are second only to oral and genital infections in frequency. Primary infections are associated with keratoconjunctivitis and are often bilateral whereas recurrences are usually unilateral and result in dendritic ulcers or stromal involvement. Repeated recurrences may lead to scarring and opacification of the cornea, and consequent sight impairment.

Invasion of the central nervous system (CNS) is manifest as herpes encephalitis, a cytolytic infection, primarily of neurons, with a propensity to focus in the temporal lobes (see Infections of the central nervous system). Untreated, the disease has a mortality of >70 percent and most survivors are neurologically impaired. All age groups are susceptible but the disease is rare; about one case per million population is reported each year in the UK and the USA. Symptoms generally begin with fever and headache, rapidly followed by disorientation and progressive deterioration in consciousness, but the symptoms are not diagnostic and can be confused with other syndromes. Predisposing factors are unknown. Herpes encephalitis can apparently result from primary or recurrent infection (Nahmias et al. 1982; Whitley et al. 1982), but the route to the CNS is uncertain. A focal encephalitis, similar to that observed in humans, results from infection of mice by the olfactory route (Anderson and Field 1983). Aciclovir therapy has greatly reduced the morbidity and mortality of herpes encephalitis but effective treatment depends on prompt diagnosis.

The neonate is highly susceptible to HSV infection, and neonatal infection is frequently fatal. The disease presents classically as a generalized infection affecting multiple organs, including the lung, liver, adrenals, CNS, and skin, but in some cases the infection is more limited, involving the skin or the CNS or both. The prognosis is very poor for those with disseminated or CNS infection.

In the USA neonatal herpes is estimated to occur with an incidence of 1 per 2 000–5 000 deliveries and is perceived as a major public health problem, but in the UK the disease is rare (Sullivan-Bolyai et al. 1983; PHLS Report 1987), an unexplained discrepancy that cannot be accounted for by differences in the overall frequency of genital herpes in the two populations. The infection is most commonly acquired during birth from a genital infection of the mother but infections in utero and in the immediate postnatal period have also been documented and probably represent a significant proportion of the total. Primary infection in the mother close to term presents a much higher risk to the neonate than does recurrent infection (Prober et al. 1987), probably owing to the higher virus titers present during primary infection and perhaps to the protective effect of maternal antibody present in the neonate exposed to recurrent infection. Delivery by cesarean section is usually recommended when genital lesions are present at term. Superficial damage to the skin by fetal scalp monitors is thought to provide the virus with a route of entry, and the use of scalp monitors is contraindicated if the mother has a history of recurrent genital infection.

Not surprisingly, the immunocompromised patient has an increased susceptibility to HSV infection. The most common manifestation is a reduced capacity to control recurrent oral lesions which occur more frequently and spread more widely on the head and neck and to the respiratory tract (e.g. Smyth et al. 1990). These infections resolve slowly, if at all, in the absence of therapy. Although these infections can be very severe, they are nevertheless limited to the skin and mucosa, even in profoundly immunosuppressed patients. Disseminated, generalized infection, as seen in the neonate, has been reported in adults very rarely.

Epidemiology

A wide range of mammalian species can be infected experimentally with HSV but there is no evidence that this occurs naturally. Humans are the only natural host, and latent virus in trigeminal and sacral ganglia is the reservoir. The source of transmitted virus is oral or genital secretions, and transmission requires contact. There is no seasonal variation in disease incidence. Because HSV-2 is primarily a sexually transmitted disease and occurs only rarely as an oral infection, evidence of HSV-2 infection is found almost exclusively in adolescents and adults, whereas HSV-1 is a common infection of childhood. Despite this straightforward picture, which emerges from a large number of seroepidemiological and virological studies, precise data on the incidence of HSV-1 and HSV-2 infections in different study populations have been difficult to obtain because of the high proportion of asymptomatic infections and problems in distinguishing antibodies to the two subtypes.

In many populations, virtually all children are infected with HSV-1 during the first 5 years of life, but seroconversion rates vary greatly with geographical area and socioeconomic group. In higher socioeconomic groups in industrialized countries, seroconversion may be as low as 20 percent during the first 5 years, rising to 40–60 percent during adolescence and early adulthood. Young children secrete virus asymptomatically more frequently and for much more prolonged periods than seropositive adults; this, together with higher levels of contact activity, probably accounts for the high attack rates in this group. Seroepidemiological surveys emphasize the view that HSV-2 is transmitted primarily by the sexual route: antibodies specific for HSV-2 are virtually nonexistent in nuns but are found in the majority of prostitutes, and the appearance of HSV-2 antibodies correlates with the onset of sexual activity. The reported overall incidence of HSV-2 antibodies in the adult population varies in different studies, and many historical surveys suffer from technical problems associated with the serological crossreactivity of HSV-1 and HSV-2. More recent studies estimate that 15–25 percent of the adult US population is infected with HSV-2, and broadly similar data have been obtained in the UK (Ades et al. 1989), though prevalence rates vary significantly among different ethnic groups. As noted above, HSV-1 can also be transmitted by the sexual route, and in some studies nearly 50 percent of genital isolates were of this type (Ross et al. 1993). It is supposed, though not proven, that the large number of HSV-1 genital infections and the occasional HSV-2 oral infection result from orogenital sex.

Pathology and pathogenesis

The portal of entry in primary infection is the damaged skin or mucosa and the classic lesion is a vesicle beneath the keratinized squamous epithelial cells (Figure 2).

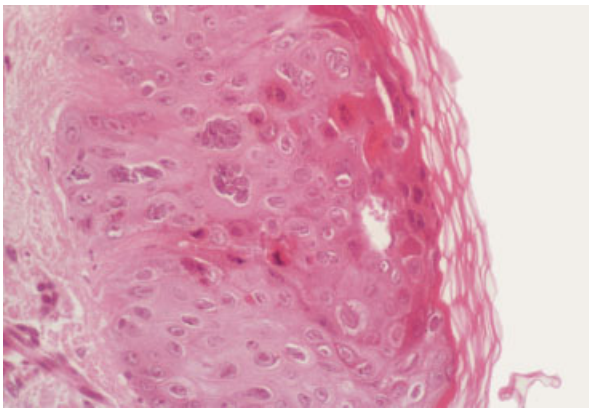

Figure 2 *Herpes simplex vesicle: infection is limited to epithelial cells, which become disorganized and exhibit characteristic nuclear inclusions. Multinuclear cells result from cell fusion. The lesion shown is at a relatively early state and contains very few inflammatory cells. (Photograph courtesy of Dr. Jane Sterling, Addenbrooke's Hospital, Cambridge, UK.)*

The infection of epithelial cells is cytolytic; the cells lose adhesion, occasionally become multinucleate as a result of virus-induced cell fusion and contain Cowdry type A nuclear inclusions. The vesicle drains and the lesion crusts before healing occurs, sometimes with residual scarring, and draining lymph nodes are commonly enlarged during this process. Recurrent lesions are morphologically and histologically similar but are usually less extensive, and lymph node swelling is inapparent. In the immune competent patient the lesion resolves within 7–10 days of its appearance.

LATENCY AND REACTIVATION

During primary infection of the skin or mucosa the virus enters sensory nerve endings and is transported by fast retrograde axonal flow to the neuronal bodies of the dorsal root ganglia innervating the site of infection. In animal models this is followed by a period of limited virus replication in the ganglia, during which virus antigen can be detected in a small number of neurons. Within about 10 days, no infectious virus can be detected in the ganglia or at the site of inoculation, but the presence of latent virus can be detected for the lifetime of the infected animal by dissection and in vitro culture of the relevant sensory ganglia (Stevens and Cook 1971; Hill et al. 1975). Similarly, 'in vitro reactivation' of latent virus can be achieved by culture of trigeminal ganglia from cadavers of HSV-1 seropositive humans.

Many lines of evidence show that HSV establishes a true latent infection rather than a low level chronic infection. Mutant viruses that are incapable of replicating at the internal temperature of the mouse establish and maintain latency (McLennan and Darby 1980). Long-term treatment of infected mice or humans with aciclovir does not cure latency (Fife et al. 1994); the state of the viral genome in latent infection is unique. HSV DNA within virus particles is a linear molecule whereas viral DNA in latently infected ganglia is endless and is thought to be present as a circular episome (Mellerick and Fraser 1987). The latently infected ganglion contains a unique set of transcripts, the 'latency-associated transcripts' (LAT) synthesized from a single promoter (the LAT promoter) situated in the repeat sequences flanking the unique long region of the viral genome (Stevens et al. 1987). These transcripts are readily detected by in situ hybridization in latently infected human trigeminal ganglia or in ganglia from experimental animals, and they are found exclusively in neurons (Figure 3) – consistent with other evidence that this cell type is the site of latent infection. The function of the latency-associated transcripts is uncertain. Mutations that modify the transcripts, or abolish their synthesis, do not prevent the virus from establishing or maintaining latent infection in animal models. Indeed, despite extensive study, no HSV gene has been identified that is essential for latent infection, and one view is that latency requires no gene function but occurs by default if the productive cycle fails. On this supposition the transcriptional machinery of the neuron is the key factor in latency and reactivation: if the neuron fails to transcribe the viral immediate–early genes (see Herpesviruses: general properties), the productive cycle cannot be initiated and the viral genome is latent by default, but at some later time perturbation of the sensory nerve may change the transcriptional program of the neuron. The viral immediate–early genes may then be expressed, the productive cycle is initiated, and the latent virus reactivates. The evidence for this mechanism is largely negative but is consistent with the characteristics of an in vitro latency model in which the level of expression of one of the immediate–early genes appears to be a key factor in determining whether the virus enters the lytic cycle or remains latent (Preston 2000). Evidence is accumulating that the LAT has anti-apoptotic functions and this protects the neuron during establishment of latency and during reactivation. This would account for the fact that HSV mutants unable to synthesize LATs are capable of establishing latency but do so with reduced frequency and reactivate less efficiently (Jones 2003).

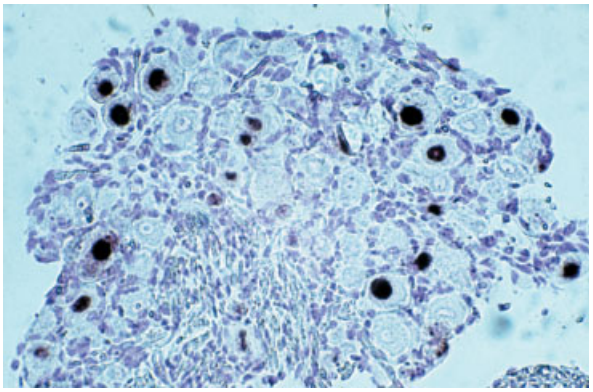

Figure 3 *Virus-specific transcripts in a sensory ganglion from a mouse latently infected with* HSV-1. *LATs are detected by hybridization in situ within the nuclei of a minority of sensory neurons. No viral antigens, productive cycle transcripts or virus particles are detectable. Latent infection of the tissue can be demonstrated by explant culture. (Photograph courtesy of Dr. R Lachmann, Department of Pathology, University of Cambridge.)*

Perturbation of the sensory nerve can induce HSV reactivation, an observation first made by Cushing (1905), who noted the frequent appearance of cold sores after sectioning the posterior sensory root of the trigeminal ganglion, a result that has been confirmed in animal models. Furthermore, virus in latently infected rat sympathetic ganglia cultured in vitro reactivates after withdrawal of nerve growth factor (Wilcox et al. 1990). Nevertheless, the specific neuronal changes that lead to reactivation are unknown. A wide variety of stimuli provoke clinical recurrence but, as noted earlier, many of these stimuli may act to enhance virus replication at

the periphery rather than to induce reactivation in the ganglion. What is certain is that reactivation and virus shedding are much more common than clinical recurrence. The fate of the neuron in which reactivation occurs is also unknown. It is axiomatic of HSV infection that the productive cycle is cytolytic, yet reactivation and seeding of epithelium with infectious particles must require productive infection in the neuron. There is no evidence of sensory loss, even in patients who suffer frequent recurrences over a very long period, and it is uncertain whether reactivation results in the loss of the neuron or if, unlike other cell types, the neuron can survive virus replication.

Immune response

HSV infection in humans induces a vigorous humoral and cell-mediated response, but studies of the details are confounded by the very large number of antigens specified by the virus (>70) and by the technical problem of examining the response to primary infection. Most studies in humans have been of the response to latent infection or recurrent disease, whereas much information on the primary response derives from experiments in inbred mice.

Infection is followed within a few days by the appearance of IgM antibodies, closely followed by IgG and IgA. IgG persists indefinitely and antibodies against at least 30 different viral polypeptides have been identified. The surface glycoproteins of the virus (of which there are at least 10) are among the most immunogenic and these are also the targets for complement-dependent and complement-independent antibody-mediated neutralization. Glycoprotein D, delivered as a subunit protein or using live vectors, is probably the most potent inducer of neutralizing antibody and, in humans, anti-gD titers correlate with serum neutralizing titers. The role of antibody in infection is, however, uncertain. High levels of passive antibody protect mice from infection and modulate infection (Simmons and Nash 1985) but B-cell-deficient mice recover more or less normally from infection and agammaglobulinemic patients do not suffer particularly severe HSV infections (Corey and Spear 1986; Simmons and Nash 1987). While antibody can protect against infection, at least in mice, the cell-mediated responses are of central importance in controlling an established infection since, in humans and in mice, T-cell deficiencies result in severe disease and inefficient clearance of virus. The importance of different T-cell subsets and of innate cellular defense mechanisms varies in mice, depending on the strain and infection route. Nevertheless, $CD4^+$ T cells predominate in clearance of infection from the skin and mucosa (Nash and Gell 1983; Schmid 1988), whereas classic major histocompatibility complex (MHC) class I-restricted cytotoxic T cells are readily detected in mice but difficult to detect in humans. There is evidence that $CD8^+$ T cells control HSV in the nervous system but by a cytokine-mediated mechanism rather than by direct cytotoxicity (Simmons and Tscharke 1992). Innate defenses are also likely to be of central importance. HSV has a very broad cell tropism yet systemic generalized disease is found almost exclusively in the neonate and not in profoundly immunosuppressed children or adults. In mice, interferon responses, NK cell activity, and macrophage function have all been shown to control HSV infection, and deficiencies in these defenses may contribute to the susceptibility of the neonate (Cunningham and Merigan 1983; Lopez 1985; Wu and Morahan 1992). Severe HSV infection in a child with an NK-cell deficiency has been reported (Biron et al. 1989) but there are conflicting data on the importance of NK cells in controlling HSV (Bukowski and Welsh 1986).

It is worth reiterating that studies of the response to HSV in the mouse are almost exclusively concerned with primary infections. Recurrent infections do not occur in inbred mice, and in guinea pigs and rabbits, which exhibit recurrent disease, the immune response is not amenable to detailed analysis. In humans, recurrent episodes are not usually accompanied by significant changes in antibody levels but changes in T-cell proliferative responses have been reported. Comparisons of immune responses in seropositive patients with and without recurrent disease have given no indication of a consistent quantitative or qualitative difference in response in these two groups, and it may be that other factors, such as latent virus load, rather than the immune response, determine recurrence frequency. Nevertheless, the fact that recurrences usually decrease in frequency with time and that immunocompromised patients suffer more recurrent episodes suggests that recurrences can be suppressed by an acquired immune response. This is an issue of some consequence because the identification of the key elements of the response might allow the development of immunotherapeutic approaches to the prevention of recurrent disease. Immune responses to HSV infection have been reviewed by Daheshia et al. (1998) and Nash (2000).

HSV has evolved a number of mechanisms to evade the immune response. Glycoprotein C binds to the C3b complement component and inhibits the complement cascade (Fries et al. 1986). The glycoprotein E/glycoprotein I complex binds to Fc regions of IgG and inhibits Fc-mediated effector mechanisms (Frank and Friedman 1989; Bell et al. 1990). The US12 gene product binds the transporter associated with antigen processing (TAP) and prevents antigen presentation on MHC class I molecules (York et al. 1994; Hill et al. 1995). None of these evasion mechanisms operates efficiently in mice, and there is good reason to doubt, therefore, whether immune control of HSV in mice precisely mimics events in humans.

Diagnosis

HSV infection is usually diagnosed by virus culture or by polymerase chain reaction (PCR). The virus is labile and sensitive to desiccation, so swabs should be kept in transport medium and cultured as soon as possible. HSV grows rapidly in a variety of fibroblasts and epithelial cell types, causing a characteristic cell rounding or 'ballooning' which develops within a few days and spreads rapidly. Unlike laboratory-passaged strains, which are often syncytial, fresh isolates cause little, if any, cell fusion. In combination with clinical presentation, the development of characteristic cytopathic effect (CPE) in culture is usually sufficient for confident diagnosis, but if necessary this can be confirmed by a variety of immunocytochemical or antigen capture tests. The sensitivity of these tests allows diagnosis within 24 hours of culture, before extensive CPE develops, and also allows distinction between HSV-1 and HSV-2 isolates with type-specific reagents. Primary infections can also be diagnosed serologically by the detection of virus-specific IgM or by the rising IgG titer. A variety of tests are available but enzyme-linked immunosorbent assay (ELISA) is the most widely used. The diagnosis of herpes encephalitis presents a special problem and rapid diagnosis is of importance because of the urgency of appropriate treatment. Diagnosis used to require the identification of virus or virus antigen in brain biopsies, but is now achieved by detection of viral DNA in the cerebrospinal fluid using PCR (Lakeman et al. 1995). The sample must, however, be taken before aciclovir therapy is begun.

The distinction between serum antibodies to HSV-1 and HSV-2 is rarely of clinical relevance but is crucial in seroepidemiological surveys of infection incidence. Serum against either virus reacts with both types in all assays, and historical methods of measuring type-specific antibody such as cross-adsorption and kinetic neutralization were time-consuming and unreliable. More recent methods are based on the observation that glycoprotein G of HSV-1 and HSV-2 is highly immunogenic and shows very little antigenic cross-reaction. Glycoprotein G, purified from infected cells or prepared as a recombinant protein, can therefore be used as a target for type-specific antibody detection using standard enzyme-linked assays (Lee et al. 1986; Sanchez-Martinez et al. 1991; Ho et al. 1992). Although these methods are clearly an improvement on previous approaches, discrepant results have been reported when compared with western blot assays, which are generally regarded as well validated but relatively tedious (Ashley et al. 1988; Safrin et al. 1992).

Control

Like other nonepidemic diseases transmitted by contact, HSV infection cannot be controlled by public health measures. Reduction in sexual transmission can be attempted by public education on the risks of unprotected sex. Despite education campaigns aimed at reducing the spread of the human immunodeficiency virus (HIV), the reported incidence of genital herpes has risen in the UK (Barton 1995), though it is questionable whether this represents a real increase in transmission frequency.

VACCINATION

No licensed vaccine is currently available for prophylaxis against HSV. Indeed, the fact that reinfection is possible and that restimulation of the response by a recurrence does not prevent further recurrences has been used to argue that the development of a successful vaccine is impossible. Two lines of evidence suggest that this is not so. First, infection by HSV-1 decreases the incidence and severity of subsequent HSV-2 genital infections (Mertz et al. 1992). Second, a variety of immunogens, including killed virus, glycoprotein subunits, viral antigens expressed by live vectors, and attenuated or disabled HSV, will all protect mice and guinea pigs from challenge infection. As noted previously, the virus has evolved immune evasion mechanisms that do not operate efficiently in rodents, and data obtained from animal models must be treated with caution. Nevertheless, these results suggest that a protective response can be mounted, and the successful development of attenuated vaccines against other human and animal alphaherpesviruses gives some confidence in the principle of vaccination against HSV. Many candidate vaccines have been developed based on the production of immunogenic subunits or the construction of rationally attenuated or disabled live HSV. A number of candidates have been studied in clinical trials, though most trials tested therapeutic benefit against established recurrent infection rather than prophylactic efficacy. The difficulty of conducting a fully controlled prophylactic trial, and in particular of monitoring subclinical infection in participants, is illustrated by the study conducted by Mertz et al. (1990). Progress and prospects in the development of HSV vaccines has been reviewed by Whitley and Roizman (2002) and Koelle and Corey (2003).

CHEMOTHERAPY

HSV, together with other human herpesviruses, is among the most studied targets for antiviral chemotherapy, a subject covered in detail elsewhere (see Immunoprophylaxis of viral diseases). Nucleoside analogues such as idoxuridine, trifluorodeoxyuridine, and adenine arabinoside were used for many years to inhibit viral DNA replication, but these analogues lacked selectivity and their cytotoxicity limited their use to topical treatment in all but the most life-threatening circumstances. The development of aciclovir transformed the treatment of HSV infections. Aciclovir

is a guanosine analogue in which the sugar is replaced by an acyclic ring lacking the 2′ and 3′ carbons. The analogue is converted to the 5′-monophosphate by the HSV-specific thymidine kinase (TK) and then to the triphosphate by cellular kinases. The viral DNA polymerase incorporates the triphosphate into the growing viral DNA where it acts as a chain terminator. The inability of host-cell kinases to convert aciclovir into its monophosphate accounts primarily for its selective action against HSV-infected cells and its nontoxicity, although, in addition, the viral DNA polymerase has a higher affinity than its cellular counterpart for the triphosphate. Aciclovir is available in a number of formulations and can be administered topically, orally, or intravenously. Its oral bioavailability is 15–30 percent and plasma half-life about 2–3 hours, so relatively frequent doses are required to maintain therapeutic concentration. The route of administration depends on the site and severity of infection: topical application is used for eye infections and oral lesions, oral administration for severe genital infections and intravenous administration for encephalitis and life-threatening infection of immunocompromised patients. A cream formulation is available without a prescription ('over the counter') in the UK for cold sore treatment, but not in the USA.

Mutants of HSV resistant to aciclovir arise readily in culture, almost invariably due to loss of a functional virus TK gene. This gene function is irrelevant for virus growth in vitro but its loss results in severe attenuation in vivo. Alternative routes to resistance are point mutations in the TK gene or DNA polymerase gene that reduce enzyme affinity for aciclovir and aciclovir triphosphate, respectively (Furman et al. 1981; Larder et al. 1983; Larder and Darby 1984). Resistance to therapy has been observed most frequently in immunocompromised patients receiving long-term therapy. The mutants isolated from these patients include those with altered TK or DNA polymerase enzymes, but the most frequent finding is of a heterogeneous population of viruses with a range of TK activities from entirely deficient to almost normal. The basis of this form of resistance is uncertain, but it is known that TK-negative viruses can be complemented, in vivo, by a wild-type virus (Efstathiou et al. 1989) and it appears that aciclovir selective pressure, particularly in the immunocompromised, can maintain a dynamic mixture of TK-kinase-positive and -negative viruses.

During the past 10 years, a second generation of anti-herpes drugs based on aciclovir, with the same mechanism of action, has been developed (famciclovir, valaciclovir). A second class of analogues with anti-HSV activity are pyrophosphate analogues which act as inhibitors of HSV DNA polymerase. Foscarnet is the sole example in clinical use. Topical application is well tolerated but intravenous administration can cause nephrotoxicity and severe nausea. Foscarnet has no advantage over aciclovir but is of value in treating aciclovir-resistant infections.

Finally, anti-herpes chemotherapy suppresses virus growth but has no apparent effect on latent infection. Patients who have been treated with aciclovir continuously for as long as 6 years experience recurrences after drug withdrawal (Fife et al. 1994).

VARICELLA-ZOSTER VIRUS

It has been recognized for many years that varicella (chickenpox) and zoster (shingles) are caused by the same virus and that zoster results from the reactivation of an endogenous virus acquired during primary varicella. Our understanding of the pathogenesis of VZV derives almost entirely from clinical studies. The virus is highly species-specific in vivo, though it has been adapted to grow in guinea-pig cells and isolates thus adapted will cause a varicella-like disease in guinea pigs (Pavan-Langston and Dunkel 1989). A closely related virus, simian varicella virus, has been isolated from Old World monkeys (Soike et al. 1984; Padovan and Cantrell 1986).

Clinical manifestations

VARICELLA

Chickenpox is one of the common childhood exanthems, affecting most children during their early school years. The incubation period is about 2 weeks, after which the characteristic rash appears, composed of macules which rapidly develop into fluid-filled vesicles. These vesicles crust within a few days and heal, usually without scarring, within a few weeks. The lesions appear in crops, so any one area will contain macules, vesicles, and crusted lesions (Figure 4). The rash tends to be centripetal and is variable in severity; a high density of vesicles is present on all parts of the skin and on mucosal membranes of the mouth and genitalia in some cases,

Figure 4 *Chickenpox macules and vesicles. (Photograph courtesy of Dr. Jane Sterling, Addenbrooke's Hospital, Cambridge, UK: Copyright Addenbrooke's NHS Trust.)*

while at the other extreme the number of vesicles may be very small or the infection inapparent. The accompanying fever is usually low grade, but reflects the severity of the rash and persists as long as new lesions continue to appear. The incidence of complications in normal children is low, the most common problem being secondary infection of lesions and consequent scarring, a problem that can usually be solved by antibiotic treatment. Central nervous system involvement is rare and may take the form of an invasive encephalitis or a transient ataxia, or may be a prelude to Reye's syndrome. Although primary varicella is usually a benign disease of the normal child, infection of malnourished children is much more severe (Salomon et al. 1966). The main groups in which complications occur are, however, the adult, the neonate, and the immunocompromised.

Infection of adults (Figure 5) is generally more severe than in children; the vesicles heal more slowly, secondary bacterial infection and scarring are more common, and the accompanying fever is higher and more prolonged. The most serious complication is varicella pneumonia which appears a few days after onset of the rash and usually resolves in the immunocompetent patient, though there may be residual nodular calcification. Pregnant women are thought to be particularly prone to varicella pneumonia, symptomatic pneumonia being reported in as many as 10 percent of primary varicella cases, with occasional mortality, though some studies report much lower frequencies of morbidity and mortality (Brunell 1992).

Primary varicella during pregnancy places the fetus at risk from two routes: infection in utero and neonatal infection. Infection in utero can result in congenital malformations which include limb hypoplasia, cicatrizing skin lesions, and sensory and motor deficiencies. These conditions are associated with maternal infection during the first 20 weeks of pregnancy. Primary varicella in the mother close to term is associated with severe disease in the neonate: symptoms appear in the infant about 7 days after birth and include pneumonia and visceral involvement, particularly of the liver. A full account of maternal, fetal and neonatal infections with VZV is given in Infections of the fetus and neonate, other than rubella.

Varicella is severe and often life-threatening in immunocompromised patients. Leukemic children form a major risk group but patients undergoing chemotherapy or steroid treatment or who have any acquired or inborn immune deficiency are at risk. The most common complications are varicella pneumonia, visceral involvement, and CNS infection, but also include hemorrhagic varicella ranging from bleeding into lesions to purpura fulminans (Feldman et al. 1975).

HERPES ZOSTER

Like HSV, VZV establishes a life-long latent infection of sensory dorsal root ganglia, but, because VZV is disseminated, latency is established in multiple ganglia. Reactivation and recurrences take the form of a unilateral rash, herpes zoster, limited to a single dermatome, the area of skin innervated by a single sensory ganglion. The rash appears most commonly in the thoracic dermatomes (Figure 6), reflecting the high density of vesicles in this area during primary varicella, but also occurs (in about 10 percent of cases) as cranial zoster, often with eye involvement and may, in rare instances, appear on almost any part of the skin or mucosa (Figure 7). In healthy people zoster is relatively uncommon; many people never experience it and few have more than one or two episodes, although it is common to suffer an episode in old age.

Figure 5 *Adult with chickenpox: slow healing and resolution of vesicles. (Photograph courtesy of Dr. Jane Sterling, Addenbrooke's Hospital, Cambridge, UK: Copyright Addenbrooke's NHS Trust.)*

Figure 6 *Thoracic zoster. (Photograph courtesy of Dr. Jane Sterling, Addenbrooke's Hospital, Cambridge, UK: Copyright Addenbrooke's NHS Trust.)*

Figure 7 *Mandibular zoster. (Photograph courtesy of Dr. Jane Sterling, Addenbrooke's Hospital, Cambridge, UK: Copyright Addenbrooke's NHS Trust.)*

The rash of herpes zoster is usually preceded by pain in the involved dermatome, which begins a few days before the rash appears and remains during its development. The rash is composed of varicella-like vesicles but often so densely packed as to appear as a continuous area of eruption (Figure 6). The rash develops over the course of about a week and usually crusts and heals in 2–3 weeks, but the course is variable and, particularly in the elderly, the symptoms are often more severe and prolonged. Unlike oral HSV recurrences, no stimuli have been identified that provoke zoster. The susceptibility of the elderly to zoster has been interpreted to reflect a waning immunity, a view consistent with the increased frequency of zoster in the immunocompromised patient, but it is probable that the immune system controls reactivated virus rather than prevents reactivation. The detection of VZV DNA fragments in circulating mononuclear cells of healthy patients (Gilden et al. 1983) implies that reactivation of latent virus may be much more common than clinical zoster. *Zoster sine herpete* is the term applied to a syndrome in which a typical zoster prodrome is unaccompanied by the subsequent development of a zoster rash (Easton 1970; Gilden et al. 1992a).

Complications associated with zoster are uncommon in children and young adults but occur frequently in the elderly and the immunocompromised. Post-herpetic neuralgia is the most common complication and is defined as pain lasting longer than 1 month after lesions heal. It is rare in patients under 40 years of age but occurs in 50 percent of patients over 60 and, although the pain usually resolves in a few months, it can last for a year or more and is a major cause of morbidity in the elderly. It is most frequently associated with zoster of the ophthalmic branch of the trigeminal (cranial zoster), and cases of sufficient severity and protraction may require surgical ablation of the ganglion. In some instances, anesthesia of the involved dermatome occurs and may result in residual palsy. The pathogenesis of post-herpetic neuralgia is unknown.

Other complications of zoster usually reflect underlying immunological defects. Zoster occurs with high frequency in immunocompromised patients and is unusually severe. Failure to control the recurrences is often illustrated by the spread of vesicles beyond the dermatome in which the initial rash occurs. The disease may become widely disseminated and correspond to severe varicella with involvement of the lungs or CNS. In these circumstances zoster may be fatal, most commonly as a result of pneumonia.

Epidemiology

VZV infects only humans. The reservoir is latent virus in sensory ganglia. Primary infection causes varicella, a common disease of childhood. Only a small minority of young adults remain uninfected but by late middle age infection and immunity are virtually universal in industrial societies. Infection is usually accompanied by the characteristic syndrome; asymptomatic infection does occur, but the proportion of subclinical infections is difficult to estimate and is based largely on patient recall. The disease occurs in epidemics which, in temperate zones, usually appear in late winter every 2 or 3 years in young schoolchildren. Airborne spread has been demonstrated (Gustafson et al. 1982) and the attack rate is high: more than 60 percent within households, and 20 percent in society as a whole (Yorke and London 1973), a rate lower than observed for measles. However, data collected before the advent of measles vaccination revealed that more young adults had been infected with VZV than with measles, a reflection of the fact that measles infection occurs almost exclusively during epidemics whereas varicella infection often occurs in unrecorded 'mini-epidemics' or as isolated cases resulting from contact with zoster. The risk of varicella infection through contact with zoster within a household has been estimated to be about threefold lower than through contact with varicella (Hope-Simpson 1965).

Zoster exhibits no seasonal incidence, and is not correlated with outbreaks of varicella. Despite reports of 'outbreaks' of zoster, all evidence favors the view that zoster is the reactivation of latent virus rather than a transmissible syndrome and reports of 'outbreaks' almost certainly refer to statistical anomalies. In immunocompetent people the incidence of zoster correlates only with age, the disease incidence being approximately proportional to the age of the study group.

Pathogenesis and pathology

Like other relatively benign diseases of humans, varicella pathogenesis cannot be studied in detail in the normal host. Our understanding of VZV pathogenesis derives, at least in part, from studies of severe or fatal disease and by analogy with other, better studied, exanthems. The route of entry is probably the upper respiratory tract or oropharynx where replication in epithelial cells occurs. During the incubation period of about 2 weeks, cell-associated virus can be detected in the bloodstream, primarily in mononuclear cells, and skin lesions are then initiated by infection of capillary endothelial cells. Whether the systemic amplification of virus is limited to circulating cells and capillary endothelium in the normal individual is unknown. In fatal varicella of the newborn or immunosuppressed, productive lesions can be found on all mucosal surfaces and in the parenchyma of almost every organ, and it is probable that limited replication at these sites contributes to the viremia in normal benign infection. The cutaneous vesicles of varicella are histologically similar to those of herpes simplex. Vesicles on mucosal surfaces rapidly develop into shallow ulcers. The vesicle contains large numbers of free virus particles, suggesting that replication in epithelial cells results in secretion of free virus, whereas in most cell types VZV is strongly cell associated. The production of free virus in the oral cavity and upper respiratory tract is the probable major source of transmission. The patient is infectious for a few days before lesions appear until a few days after new lesions cease to appear.

The virus establishes latent infection in sensory ganglia. VZV DNA can be detected in the thoracic ganglia of seropositive cadavers, and similar results have been obtained with simian varicella virus (Gilden et al. 1983; Mahalingham et al. 1991). By analogy with HSV, access to the ganglia is assumed to be from the skin via sensory nerve endings, but a hematogenous route cannot be excluded. VZV latency is poorly understood by comparison with HSV latency. The virus has not been reactivated from human ganglia by culture in vitro, the physical state of the viral genome has not been ascertained, and the pattern of transcription during latency, in contrast to HSV, appears to involve the immediate–early productive cycle genes (reviewed by Gilden et al. 1992b). Indeed, there is some disagreement as to the cell type in which latent infection is established, and true latency, as opposed to chronic infection, is not proven (Gilden et al. 1987; Croen et al. 1988). Recurrent infection with herpes zoster, is, by analogy with HSV, assumed to result from reactivation of latent virus in a sensory ganglion and seeding of infectious virions into epithelium via sensory nerve endings, a view entirely consistent with the appearance of zoster within a single dermatome. The details of these events are uncertain. As noted earlier (see section on Herpes zoster), clinical zoster is an infrequent event and most triggering conditions, such as cytotoxic drug treatment, lymphoma, or heavy metal poisoning, are immunosuppressive, suggesting a failure to control reactivated virus rather than stimulating reactivation. The frequency of reactivation rather than recurrence is unknown. The pain associated with zoster and the frequency and prolonged nature of postherpetic neuralgia distinguish VZV recurrences from those of HSV, and it is proposed that these features reflect more widespread growth and consequent inflammation in sensory ganglia during VZV recurrence. This plausible explanation implies a quantitative difference between VZV and HSV recurrence but fundamental differences in the nature of latency, reactivation, and recurrence of the two viruses cannot be excluded.

Immune response

Primary infection results in life-long immunity to exogenous reinfection. Humoral response, T-cell proliferative responses and cytotoxic T-cell responses are all detectable soon after symptoms appear, rise during convalescence, and remain detectable throughout life. Recurrence is accompanied by a pronounced anamnestic response, an observation in contrast to HSV recurrence. Antibodies to at least 35 different VZV antigens have been identified in convalescent sera, including neutralizing antibodies directed against viral glycoproteins, but, despite the use of passive immunoglobulin in therapy, there is little evidence that humoral responses are important in controlling infection. No correlation has been found between titer or spectrum of VZV-specific antibodies and severity of varicella or the recurrence or severity of zoster (Brunell et al. 1987). Agammaglobulinemic patients do not suffer from unusually severe varicella or from frequent or severe zoster. By contrast, many studies have demonstrated a correlation with deficiencies in cell-mediated immunity and the severity of varicella infection and the frequency and severity of zoster. T-cell proliferative responses, cytotoxic T-cell responses and interferon responses are all detected in human infection and in animal models (Arvin 1992; Rotbart et al. 1993). Responses to individual virus antigens, both structural and immediate early nonstructural proteins, have been found, but the importance of particular responses to individual antigens has yet to be determined. The decline in cell-mediated responses to VZV in the elderly is thought to be responsible for the increased frequency of zoster in this group (Miller 1980; Berger et al. 1981), and is consistent with the occurrence of zoster in immunocompromised patients. The maintenance of adequate levels of cell-mediated immunity to varicella in the population is therefore important but it is uncertain whether restimulation of the response occurs primarily through subclinical reactivation or

results from re-exposure to varicella. Evidence exists for both mechanisms (Meyers et al. 1980; Arvin et al. 1983), but their relative contribution is of importance in predicting the possible consequences of mass vaccination and the need to vaccinate seropositive people carrying wild VZV.

Diagnosis

Virus particles are present at high concentrations in vesicular fluid and can be cultured in a variety of human and primate cell lines. The cytopathic effect is focal and develops slowly with typical cell 'ballooning' and fusion. Immunofluorescence of infected cultures with specific antibody confirms the presence of VZV and allows more rapid diagnosis. The virus in culture is very strongly cell-associated and efficient storage of isolates requires freezing of viable infected cells. Electron microscopic examination of vesicular fluid reveals the presence of large numbers of herpesvirus particles, a method used historically to allow a rapid distinction between chickenpox and smallpox but which cannot distinguish VZV and HSV. Detection of VZV DNA by PCR is now widely used, particularly for diagnosis of severe disease where rapid differential diagnosis is required.

A wide range of serological tests for VZV-specific IgG have been described, including complement fixation, latex agglutination, radioimmunoassay, and ELISA. ELISAs for VZV-specific IgG and IgM are commercially available. A suspect rash can be confirmed as varicella by the presence of IgM or by a rising IgG titer. Zoster can be similarly confirmed because, in contrast to HSV, recurrence is usually associated with a significant rise in antibody titer. A skin test for cell-mediated immunity has been described (Kamiya et al. 1977; Takahashi et al. 1992) and is thought to provide a relevant measure of immunity to zoster.

Control

EPIDEMIOLOGICAL CONTROL

No attempt is made to limit the spread of varicella in the general population because, as a rule, acquisition of the virus early in life is preferable to infection as an adult. Within hospitals, however, VZV infection has serious consequences for high-risk groups such as premature babies, leukemic children and transplant recipients, and patient isolation may be necessary to protect these groups. Healthcare staff can be monitored for immunity to VZV, and seronegative staff who suspect they have contracted varicella or staff suffering a zoster recurrence should avoid contact with high-risk patients.

VACCINE

A live attenuated vaccine was developed in Japan by passage of the Oka strain in guinea pig cells and its efficacy was first reported by Takahashi et al. (1974). Since then the vaccine has been used extensively in normal and immunocompromised children and adults. The vaccine is licensed as a childhood vaccine in the USA and has recently been licensed in the UK for particular risk groups. Japanese and US experience with the vaccine is broadly similar (reviewed by Gershon et al. 1992 and Arvin 2001). A single vaccine dose gives >90 percent seroconversion and an 85 percent protection against subsequent varicella, which, when they occur, are mild. Both humoral and cell-mediated immunity are long-lasting but it is uncertain whether this is due to subclinical challenge with circulating virus. Vaccination of leukemic children provides similar levels of protection but vaccination of adults results in somewhat lower protection rates. There are few side effects of the vaccine in healthy children, some 5 percent suffering a mild rash occasionally accompanied by fever, but in leukemic children side effects are more noticeable, about half the vaccinees developing a rash, in some cases resembling typical varicella. Nevertheless, the vaccine-related reactions in these patients are benign compared with the risk of varicella infection. Vaccination of seropositive adults results in an enhancement of cell-mediated immunity and may therefore be of value in protecting the elderly against zoster (Berger et al. 1984; Takahashi et al. 1992).

It is not certain whether the vaccine establishes latent infection in all recipients. A few leukemic vaccinees have experienced zoster due to recurrence of the vaccine strain but these individuals suffered a varicella rash following vaccination, consistent with the expectation that latency and recurrence are related to virus load in the skin during primary infection. Because most healthy vaccinees have no rash, it is reasonable to suppose that they will not suffer recurrence, and to date this is the case. In view of its safety and efficacy, the Oka strain has been proposed for universal vaccination of children. It has been used successfully in combination with measles, mumps, and rubella vaccinations.

PASSIVE ANTIBODY

Passive immunization with specific zoster immunoglobulin (ZIG) (derived from donors with high anti-VZV titers) has been used to prevent or modify infection in high-risk patients who are thought to have come into contact with varicella or zoster (Gershon et al. 1974; Zaia et al. 1983; Berger et al. 1984; Takahashi et al. 1992). Examples include non-immune pregnant women, immunocompromised patients, premature babies in special care units, and neonates born to mothers with varicella at term.

CHEMOTHERAPY

VZV, like HSV and other alphaherpesviruses, specifies a TK and is sensitive to aciclovir. VZV is considerably less

sensitive than HSV, however, and much higher doses are required to achieve therapeutic benefit. Nevertheless, aciclovir is now widely used in the treatment of varicella and zoster (Whitley 1992, reviewed by Griffiths 1995). Treatment of uncomplicated varicella in children with oral aciclovir within 24 hours of the onset of the rash resulted in fewer skin lesions and reduced fever but the benefit is relatively small. Similar treatment of adults, who suffer more severe varicella, achieved essentially similar results but the benefit was more pronounced. Oral aciclovir is used both prophylactically and therapeutically in immunocompromised patients at risk from or suffering from varicella. Because of the relatively poor oral bioavailability of the drug, hospitalized patients with severe varicella are treated intravenously.

Oral aciclovir reduces pain and duration of the rash in zoster patients but has little or no effect on post-herpetic neuralgia. Two pro-drug derivatives of aciclovir, famciclovir, and valacilovir, with similar modes of action but different pharmacokinetic properties are now licensed for use against zoster. Their greater bioavailability offers advantages in some clinical settings (Carrington 1994; Murray 1995) (see also Antiviral chemotherapy).

Betaherpesviruses: cytomegalovirus, human herpesviruses 6 and 7

WILLIAM BRITT

Cytomegalovirus 1
Human herpesviruses 6 and 7 8
References 14

Betaherpesviruses that infect humans include human cytomegalovirus (CMV), human herpesvirus 5, human herpesvirus 6 (HHV-6), and human herpesvirus 7 (HHV-7). These viruses share many common biological characteristics, including restricted in vivo and in vitro cell tropism and an extended replicative cycle. Furthermore, productive virus replication, including the production of progeny virus is restricted to cells of host origin, suggesting that these viruses co-evolved with their animal hosts. This is perhaps best illustrated by cytomegaloviruses, a group of viruses with common replication strategies and conserved blocks of genes, but viruses from each mammalian species also encode additional viral genes unique to their species of origin. This observation suggests that these viruses have developed strategies and captured host genes that favor their replication and persistence in their specific host. Similarly, the in vitro and in vivo replication of betaherpesviruses is highly restricted to specific cell types and cells at particular stages of differentiation. They are also characteristically highly cell associated and replicate slowly as compared with alphaherpesviruses. The genome of betaherpesviruses range in size from the largest of all human herpesviruses, human CMV with a genome of nearly 260 kb pair to HHV-6 with a genome of 180 kb pairs. Of the well-studied betaherpesviruses, only human CMV and the closely related chimpanzee CMV contain repeated sequences at the termini of a unique long and short component of its genome, thereby permitting these components to be arranged in four isomeric forms, similar to the genomic organization of herpes simplex virus (Mocarski and Tan Courcelle 2001; Davison et al. 2003). The remaining members of this group of viruses have only a single genomic structure with repeats at the junction of the long and short regions of the genome. There are antigenic cross-reactivities between conserved structural and nonstructural proteins encoded by these viruses (Adler et al. 1993; Loh et al. 1994). Finally, infections caused by betaherpesviruses are usually subclinical and acquired at an early age in most populations. Life- or organ-threatening disease following infection is usually limited to immunocompromised hosts. More recently, chronic persistent infection with these viruses has been suggested to contribute to chronic inflammatory and proliferative diseases such as atherosclerosis and multiple sclerosis, and perhaps human cancers. The spectrum of disease associated with persistent infections caused by these viruses remains far from being fully defined.

CYTOMEGALOVIRUS

Infection with CMV is common in all human populations and infrequently associated with symptomatic illness in normal hosts. In contrast, it is a major cause of multi-organ disease in immunocompromised patients, the severity of disease being related to the degree of immunosuppression. Permissive infection in tissue culture is restricted to a very limited number of cell types, and then only in cells of human origin. CMV infections in susceptible hosts are widespread with involvement of all organ systems. Although most investigators believe that CMV can establish a persistent infection and early studies utilizing murine CMV

demonstrated a latent infection, only relatively recently have investigators demonstrated a true latent infection with human CMV (Jordan 1983; Soderberg-Naucler et al. 1997). The role of latent infection in the transmission of CMVs by blood or during allograft transplantation is well accepted; however, the importance of latent versus a persistent productive infection in the maintenance of the virus in the individual and a population remains unclear. Finally, it is of some interest that human CMV can be found in tissue from a variety of inflammatory and neoplastic diseases, raising the possibility that this virus may directly or indirectly contribute to chronic inflammatory disease and cancer.

Clinical manifestations

Although CMV rarely causes symptomatic infection in normal hosts, it has been estimated to cause between 20 and 50 percent of cases of heterophile-negative infectious mononucleosis (Klemola et al. 1970). A characteristic syndrome of fever, hepatitis, and atypical lymphocytosis following administration of blood products for cardiac surgery (postperfusion syndrome) has been attributed to CMV and represents virus transmission from blood products (Perillie and Glenn 1962; Reyman 1966). Other disease states including rheumatological diseases have been linked to CMV, although the biological and epidemiological relevance of these associations remains unclear. Recent studies have renewed interest in a possible role of CMV in the development of atherosclerotic coronary artery disease and animal models of disease have been developed which support a potentially important role of this virus in atherosclerotic heart disease (Adam et al. 1987; Petrie et al. 1988; Speir et al. 1994; Zhou et al. 1996; Zhu et al. 1999; Streblow et al. 2001; Libby 2002). Similarly, CMV gene products and nucleic acids have been detected in autopsy tissue from human brain and colon tumors and have raised the possibility that this large DNA virus could contribute to the pathogenesis of cancer (Cobbs et al. 2002; Harkins et al. 2002). Although these findings are provocative, it is unclear whether these findings represent an association between CMV and cancer or merely represent the detection of a CMV as a passenger in these tissues.

Three groups of patients are at risk for invasive acute CMV disease: (1) newborn infants infected in utero, (2) immunocompromised allograft recipients and (3) patients with AIDS. Infants infected in utero may be born with subclinical infections or may have a constellation of clinical abnormalities characteristic of what has been termed cytomegalic inclusion disease (CID) of the newborn (Jesionek and Kiolemenoglou 1904). Clinical findings include hepatosplenomegaly, jaundice, thrombocytopenia, purpura, microcephaly, chorioretinitis and, rarely, pneumonia in approximately 10 percent of congenitally infected infants (Table 1) (McCracken et al. 1969; Boppana et al. 1992). Mortality rates range from 11 to 20 percent in symptomatic infection, and up to 50 percent of long-term survivors of symptomatic infections will have deficits in perceptual and cognitive functions (McCracken et al. 1969; Alford 1984; Boppana et al. 1992; Boppana et al. 1999). A significant number of infants with asymptomatic infections are also at risk of developmental abnormalities, hearing loss being the most common (Yow et al. 1988; Fowler et al. 1992, 1997). Persistent infection with prolonged viral shedding is nearly universal in infants with either symptomatic or asymptomatic congenital infection (Stagno et al. 1975; Alford 1984).

CMV infections in the post-transplant period are a major cause of morbidity and mortality in allograft recipients. Infections can develop following reactivation of persistent or latent virus in the previously infected recipient, as the result of reinfection by virus present in the transplanted organ, or less frequently following transfusion of blood from a CMV-infected donor. The severity of infection depends on several characteristics but the two most consistently observed risk factors for severe infection are: (1) transplantation of an organ from a previously infected donor into a CMV non-immune host and (2) significant immunosuppression, including that caused by specific therapies directed at T-lymphocyte function (Singh et al. 1988; Weir et al. 1988; Fishman and Rubin 1998; Rubin 2002). Several studies using quantita-

Table 1 *Clinical manifestations of CMV infection in different patient populations*

	Clinical manifestations	
Population	**Acute infection**	**Long term**
Immunocompetent	Subclinical infection, mononucleosis syndrome	Prolonged virus shedding; inflammatory vascular disease
Immunocompromised:		
Fetuses	Hepatitis, encephalitis, retinitis, thrombocytopenia microcephaly	Hearing loss, cognitive dysfunction, developmental delay, prolonged virus shedding
Allograft recipients	Fever, hepatitis, pneumonitis, hematological abnormalities	Graft dysfunction/loss, excessive long-term mortality; transplant vasculopathy
AIDS	Retinitis, encephalitis, colitis, oesophagitis	Vision loss, wasting syndrome, decreased survival time, encephalopathy

tive measures of CMV DNA in blood have demonstrated that the viral burden of an individual patient, regardless of assignment of risk based on donor and recipient serological status, has significant predictive value of invasive CMV disease (Cope et al. 1997; Emery et al. 2000). More recent studies in hematopoietic transplant recipients have been consistent with earlier observations suggesting that the use of steroids in the post-transplant period were associated with an increased risk invasive CMV disease, presumably as a result of lymphotoxic activity of these reagents, including their activity against natural killer cells. CMV infection in allograft recipients can range from asymptomatic excretion to fulminant multi-organ disease. The most common clinical syndrome associated with CMV infection in the post-transplant period is fever, leucopenia, and mild to inapparent hepatic dysfunction (Table 1). Pneumonia attributed to CMV in the post-transplant population continues to carry a significant mortality rate. Infection of the central nervous system (CNS), including the retina, is rare in transplant patients. Long-term effects of chronic infection in allograft recipients, especially cardiac allograft recipients, include a characteristic vascuolopathy described as transplant vascular sclerosis or transplant vasculopathy (Grattan et al. 1989; Koskinen et al. 1999; Streblow et al. 2001). This disease has been faithfully recapitulated in rodent models and disease appears directly related to CMV infection and virus-gene expression in the endothelium of the allograft (Lemstrom et al. 1997; De La Melena et al. 2001; Streblow et al. 2003). The vascular disease in the allograft has been proposed to represent an accelerated variant of atherosclerotic coronary heart disease in the normal host and may offer clues to the mechanism of virus-induced vascular disease.

In certain HIV-infected populations, the incidence of CMV infection is extraordinarily high with rates exceeding 95 percent (Drew et al. 1981; Collier et al. 1987). Prior to the widespread introduction of effective antiretroviral therapy (ART) for the control of HIV replication, CMV was the most common cause of clinically important opportunistic infection in long-lived AIDS patients in the USA (Gallant et al. 1992; Pertel et al. 1992). Although numerous reports documented CMV infection in every organ system in this patient population, the gastrointestinal tract, retina and brain represent the more commonly described sites of CMV disease (Jacobson and Mills 1988; Francis et al. 1989; Schmidbauer et al. 1989; Vinters et al. 1989; Pertel et al. 1992). Colitis, persistent diarrhea with wasting, vision-threatening retinitis, and encephalopathy are common manifestations of CMV infection in patients with end-stage HIV infections (Table 1). With the advent of multidrug therapy for the control of HIV replication, the incidence of invasive CMV disease has fallen dramatically, such that new cases of retinitis in many study populations are very infrequent and develop only in patients who either present to medical care with invasive CMV disease or fail ART.

Epidemiology

The epidemiology of CMV infections can be most readily understood by examining the sources of virus, identifying populations at risk for exposure to infectious virus, and defining patients with deficits in immunity who are at risk of severe CMV infections. CMV can be cultured from most body fluids for extended periods following primary infection with significant amounts of infectious virus being found in urine, genital secretions (including semen), saliva, and breast milk. Virus is also readily transmitted by cellular elements in blood products, especially leucocytes, and by solid organs during transplantation (Prince et al. 1971; Ho et al. 1975; Gnann et al. 1988; Bowden 1991). Periodic reactivation or persistent low-level shedding from these sites is also a characteristic of CMV-infected hosts. In fact, it could be argued that, for the human host, persistent infection in the form of continuous low level replication is likely to be more frequent than periodic reactivation from latency. Sources of infection in normal hosts include exposure to virus-infected body fluids, such as occurs in crowded living conditions in developing countries and in child-care centers in developed societies. In both situations there is frequent infection of children and of susceptible child carers (Murph et al. 1986; Pass et al. 1987; Adler 1989; Murph et al. 1998). An additional source of virus exposure in infancy is breast feeding with transmission occurring in 30–70 percent of infants breast fed by mothers with serological evidence of previous infection (Dworsky et al. 1983). In adolescents and adults, CMV infection is acquired commonly through sexual exposure (Chandler et al. 1985; Handsfield et al. 1985; Chandler et al. 1987; Collier et al. 1987; Fowler and Pass 1991). Overall, it has been estimated that the rate of infection after childhood is ca. 1 percent per year (Stagno et al. 1984). Reinfections with genetically different strains of virus has been well documented in normal hosts, including children in day care and women attending sexually transmitted disease clinics (Chandler et al. 1985; Handsfield et al. 1985; Murph et al. 1986; Collier et al. 1989; Bale et al. 1996; Boppana et al. 2001). Finally, it is also likely that normal individuals can be infected with several genetically unique strains of CMV, raising questions about the definition of protective immune reactivity in patients following an acute infection.

Clinically significant infections develop in patients with deficits in immunity resulting from pharmacological immunosuppression, acquired deficits in immunity such as HIV infection or developmental immaturity of the immune system. The natural history of CMV infection in transplant recipients suggests that infection is nearly universal in those exposed, but that clinical disease is dependent on specific risk factors. In all but bone marrow

allograft recipients, a major and perhaps the most important risk factor, is the transplantation of an organ from a donor with previous infection into a CMV non-immune recipient (Ho 1991; Rubin 2002). Disease rates as high as 70 percent in renal allograft recipients following CMV mismatched donor–recipient transplantation have been reported (Rubin 2002). In the past, mortality rates in excess of 50 percent in cardiac/lung transplants limited CMV mismatched donor–recipient transplantation in some centers (Smyth et al. 1991). As the intensity of immunosuppression increases, so does the severity of CMV infections, as illustrated by the often fatal CMV infections that occur in bone marrow allograft recipients (Meyers et al. 1982; Winston et al. 1990; Schmidt et al. 1991; Zaia 2002; Boeckh et al. 2003). More recent findings have suggested that mismatched donor: recipients loci encoding natural killer (NK) cell recognition: activation antigens may also lead to significant CMV infections in the post-transplant period. If confirmed, this finding would argue for a critical role of innate immunity in resistance to CMV disease in these patients.

The natural history of CMV infections in AIDS patients has been most closely related to the depletion of $CD4^+$ lymphocytes. Several prospective studies documented high rates of CMV shedding in almost all AIDS patients, but invasive disease was more commonly observed in patients with <50 $CD4^+$ lymphocytes/mm^3 (Gallant et al. 1992). Reinfection is common and isolation of multiple strains of virus from individual patients has been reported (Drew et al. 1984; Spector et al. 1984; Chern et al. 1998). Characteristics of CMV infection that lead to severe disease and specific organ involvement are not understood, but evidence has been presented that residual virus-specific immunity may modulate disease progression (Boppana et al. 1995; Autran et al. 1997; Komanduri et al. 1998; Alberola et al. 2000; Alberola et al. 2001).

Congenital CMV infection is the most common viral infection of the human fetus (Alford 1984). In the USA the incidence of congenital CMV infection is ca. 1 percent in live births (Fowler et al. 1993; Britt and Alford 1996). In the developing world, rates of congenital infections as high as 2–3 percent have been described, suggesting that immunity does not prevent intrauterine infection (Yamamoto et al. 2001). An estimated 10 percent of infected infants will have significant infections that result in long lasting CNS sequelae (Alford; Fowler et al. 1993; Britt and Alford 1996; Boppana et al. 1999). The characteristics of the maternal infection have been claimed to be of paramount importance to the outcome of fetal infection; pre-existing maternal immunity can limit damage to the fetus, a situation analogous to that in allograft patients (Fowler et al. 1993). Primary gestational infection with CMV results in a 35–50 percent fetal transmission rate, whereas gestational reactivation or reinfection in women with preconceptional immunity is associated with a fetal infection rate of between 1–3 percent (Alford 1984; Britt and Alford 1996). Furthermore, it is estimated that fetal infection following primary maternal infection during pregnancy results in damage three times more often than infection that follows reactivation or reinfection in women with preconceptional immunity (Fowler et al. 1993). More recent findings have challenged these claims. These data include the finding that maternal reinfections with a genetically different strain of CMV do occur at a significant rate (10–12 percent) and that maternal reinfections can lead to damaging congenital infection (Ahlfors et al. 1999; Boppana et al. 2001). Furthermore, at least two different groups of investigators have reported that congenital infections following non-primary maternal infections can result in a similar incidence of long term sequelae as observed in infants infected as a result of primary maternal infections during pregnancy (Ahlfors et al. 1999, 2001; Boppana et al. 1999). Naturally acquired intrapartum or postnatal CMV infection in normal newborn infants has not been associated with severe infections and the permanent sequelae characteristic of infants infected in utero (see Table 2) (Alford 1984; Britt and Alford 1996).

Pathogenesis

In the context of currently available information, the pathogenesis of CMV infection must be viewed as a lytic viral infection resulting from a failure of host immunity to control effectively viral replication and spread. This model of CMV pathogenesis is accurately reflected by the virus burden as measured by polymerase chain reaction (PCR) or virus isolation during acute infection (Lockridge et al. 1999; Emery et al. 2000; Humar et al. 2002). However, it is almost a certainty that CMV exerts its pathogenetic potential through nonlytic mechanisms as well. These may include modulation of normal host cell functions by limited expression of its genome, and perhaps by affecting neighboring cellular functions through the induction of chemokine and cytokine production. Other pathways of host-cell damage may include the generation of host-derived immunopathological responses that result in significant organ damage, a mechanism that would explain the association of CMV with diseases such as atherosclerosis (Grattan et al. 1989; Epstein et al. 1999; Streblow et al. 2001; Libby 2002; Streblow et al. 2003). Such a mechanism has also been offered as an explanation of the severe pneumonia associated with CMV infection in bone allograft recipients and would be consistent with very early descriptions of this disease that indicated that only a few areas of the lung were infected with CMV (Myerson et al. 1984; Grundy et al. 1987). Perhaps the most convincing evidence of the importance of nonlytic mechanisms leading to disease have been provided by animal models of CMV infection leading to allograft disease, specifically transplant vascular sclerosis (Lemstrom et al. 1997;

Table 2 *Acquisitions of CMV infection in different populations*

Community acquired		Hospital acquired	
Age	**Mode of acquisition**	**Sources of CMV infections**	**Risks associated with virus transmission**
Perinatal	Intrauterine fetal infection (congenital)	Blood products	Blood products from seropositive donors
	Intrapartum		Multiple transfusions
	Breast milk acquired		White blood cell containing blood products
Infancy and childhood	Exposure to saliva and other body fluids	Allografts	Allograft from seropositive donors
			Graft rejection
Adolescence and adulthood	Sexually transmitted		
	Exposure to young children		

Koskinen et al. 1999; Streblow et al. 2003). Experimental systems including animal models have illustrated the role for virus-induced amplification of host inflammatory functions such as expression of adhesions molecules, induction of chemokine expression, and activation of transcriptional factors such as NF-κB that are central to the host inflammatory responses to virus infected cells. Such mechanisms could explain the association between CMV infection, virus gene expression in inflammatory diseases as exemplified by allograft dysfunction, and graft loss.

Pathological findings in CMV infection include evidence of virus infection in almost all organ systems (Becroft 1981; Britt and Alford 1996). Histological findings include large refractile cells (cytomegalic) with so-called owl's eye intranuclear inclusions. In some instances, organ dysfunction exceeds what would be expected from the number of infected cells detected by routine histopathological techniques. This discrepancy was initially confirmed using more sensitive techniques for demonstration of CMV (Myerson et al. 1984). Thus, the pathogenic mechanisms which account for end organ disease associated with CMV replication are unclear, as has been stated above and will likely not be explained by qualitative measures of virus within involved tissue.

Immune responses

Protective immune responses against CMV have not been definitely identified, and may not be the same in different populations. Both cellular and antibody responses to CMV participate in the immune responses that are thought to resolve infection in normal hosts (Rasmussen 1990; Walter et al. 1995; Britt and Alford 1996; Alberola et al. 2000, 2001). Most investigators who have suggested a dominant role for one arm of the immune system in protective immune responses against CMV have based these claims on findings from transplant recipients and patients with AIDS (Reusser et al. 1991; Walter et al. 1995; Autran et al. 1997; Komanduri et al. 1998; Aubert et al. 2001; Boeckh et al. 2003). In these patients, disease was associated with a decrease in either antibody or cellular responses to CMV as a result of immunosuppressive drug therapy or HIV infection. However, it must be noted that components of protective immunity in normal individuals have yet to be fully defined and that the clinical outcome in the post-transplant period that was previously attributed cellular immune effecter functions can also be related to the presence of virus neutralizing antibodies (Snydman 1993; Schoppel et al. 1997; Alberola et al. 2000). In fact, recent studies in a simian model of CMV infection in a rhesus macaques infected with a simian immunodeficiency virus have argued for a role of virus neutralizing antibodies and disease control (Kaur et al. 2003). Lastly, the importance of NK cells responses in control of murine CMV is well documented and further demonstrated by the presence of viral genes that specifically blunt the NK response (Krmpotic et al. 2002). Very recent findings would argue for a similar role of NK cells in the control of CMV infections in transplant recipients. Thus, a precise role for specific effector functions of the immune system in control of virus replication in infected host remains undefined.

In both solid organ and bone marrow transplant recipients, decreased cellular responses, especially CMV-specific $CD8^+$, MHC-restricted T lymphocyte responses, have been correlated with more severe CMV infections in the post-transplant period (Reusser et al. 1991). Reconstitution of these responses with in vitro expanded CMV-specific cytotoxic T lymphocytes has been shown to reduce post-transplant mortality secondary to CMV (Gavin et al. 1993; Walter et al. 1995). However, several studies from this same institution have shown a similar correlation of survival with the presence of virus-specific $CD4^+$-specific lymphocyte responses, especially in the late (>100 days) post-transplant period (Li et al. 1994; Walter et al. 1995; Boeckh et al. 2003). The advent of effective antiviral therapy has altered the natural history

of CMV in the transplant population such that CMV disease more commonly occurs late (180 days) in the post-transplant period (Boeckh et al. 2003). Thus, the value of a transient $CD8^+$ antiviral response provided by transferred antiviral T cells could require reassessment, particularly in light of recent experimental findings that have demonstrated the critical importance of antigen-specific $CD4^+$ responses in the maintenance of $CD8^+$ responses to infectious agents (Sun and Bevan 2003). As noted above, studies in patients with AIDS have clearly demonstrated that protective immune effector functions correlate with the restoration of CMV-specific $CD4^+$ responses (Autran et al. 1997; Komanduri et al. 1998). Findings from pregnant women have also suggested a correlation of cellular responses to CMV and intrauterine transmission, but these studies remain controversial (Gehrz et al. 1981). In AIDS patients with invasive CMV disease, cellular responses are absent because of lymphocyte depletion, yet recent improvements in the analysis of these responses have permitted the detection of CMV-specific responses in AIDS patients with severe depletion of peripheral $CD4^+$ lymphocyte numbers, indicating that only limited residual cellular immunity is required for control of CMV replication (Autran et al. 1997; Waldrop et al. 1997; Komanduri et al. 1998; O'Sullivan et al. 1999). Cellular immune responses appear to be directed primarily at the protein components of virion tegument, the products of the UL83 open reading frame (ORF), phosphoprotein 65 (pp65), and the UL32 ORF, phosphoprotein 150 (pp150). Although other CMV-encoded proteins such as the products of the *IE-1* gene elicit cellular responses, responder cell frequency analysis has indicated that these two proteins represent dominant targets of cellular immunity (Kern et al. 1999; Kern et al. 2002; Gallez-Hawkins et al. 2003). The role of cytokines in cellular responses against CMV is unknown; however, in animal models of human CMV disease, interferon (IFN)-γ has been shown to have significant antiviral activity. Finally, it has been reported that CMV infections are associated both with decreased cellular immune responses in normal individuals and with decreased CMV-specific responses in congenitally infected children (Gehrz et al. 1977; Pass et al. 1983). More recent studies using sensitive techniques such as intracellular cytokine staining following antigen exposure have demonstrated that congenitally infected infants do indeed have cellular immune responses to CMV. Depression in cellular immune responses may also contribute to superinfection with fungal pathogens in transplant recipients infected with CMV. This clinical association remains unproven but is widely held by transplant physicians.

ANTIBODY RESPONSES

Serological responses to CMV are complex because of the large number of virus proteins. Several studies have documented responses to a number of the more immunogenic proteins of CMV in both normal and immunocompromised hosts (Zaia et al. 1986; Hayes et al. 1987; Landini et al. 1988, 1993; Britt et al. 1995; Schoppel et al. 1997). These studies have provided important clues for identification of viral-encoded proteins that induce protective antibody responses as well as antibody responses which could be used in the diagnosis of acute and past CMV infections. The only well-characterized in vitro assay of antibody activity that correlates with patient outcome is virus neutralizing antibody (Adler et al. 1995; Boppana and Britt 1995; Schoppel et al. 1997). Virus-neutralizing serological responses are limited to antibodies against virus-encoded glycoproteins, as these represent the only class of viral proteins that are surface exposed in a native form. The majority of virus-neutralizing antibodies are directed against the products of the UL55 (gB), UL75 (gH), and UL73/UL100 (gM/gN) ORFs (Britt et al. 1990; Rasmussen et al. 1991). Studies have suggested that immunization with these proteins can induce neutralizing antibodies as well as antibodies reactive with the surface of virus-infected cells (Rasmussen 1990; Britt et al. 1995; Pass et al. 1999). The identification of intense and durable antibody responses to components of the viral tegument, both pp65 and pp150, has provided a rationale for including these proteins in a recombinant protein based diagnostic assay for serological reactivity to CMV (Landini 1993). Conversely, the presence of significant IgM responses to a nonstructural protein, pp50 (UL44), has led to its use as a serological target for detection of IgM and, therefore, recent infection (Landini 1993; Lazzarotto et al. 1998).

Diagnosis

The diagnosis of CMV relies either on demonstration of the agent (virus, viral proteins, nucleic acids) in body fluids, and/or tissue or on serological responses in a patient with clinical findings consistent with CMV infection. Because of the ubiquitous nature of CMV, it is important that a distinction be made between the detection of CMV and demonstration of CMV in the context of an infectious syndrome compatible with CMV. Multiple methods of recovering virus have been employed, including culture on permissive cells such as primary human fibroblasts and centrifugation enhanced culture followed by early antigen detection with monoclonal antibodies. This latter technique is widely used and can provide positive results within 24 h. In contrast, conventional tube culture may require up to 4 weeks to reveal cytopathology (Pass et al. 1995; Revello and Gerna 2002).

Techniques of viral antigen detection have been relatively limited with the exception of the antigenemia assay (van der Bij et al. 1988; Gerna et al. 1991; Miller et al. 1991; Boeckh and Bowden 1995), which uses the

immunological detection of the virus structural protein pp65 within polymorphonuclear leucocytes. Because this assay can be quantified relatively easily, it has been used to predict the likelihood of invasive disease in transplant patients and patients with AIDS (van der Bij et al. 1988; van den Berg et al. 1989). It is a widely used assay in many transplant centers and seems to be of practical value for the management of transplant patients. It is less sensitive than PCR but this may offer some advantage, including a greater positive predictive value for presence of disease because the increased sensitivity of PCR has limited its predictive value in many circumstances.

Detection of viral nucleic acids has been used extensively to document CMV infections. Dot-blot hybridization, in situ hybridization, and PCR have all been applied to clinical specimens. PCR is the most widely used assay and in certain clinical situations, such as screening newborn urine for CMV, is a highly sensitive method of diagnosis. PCR of plasma and peripheral blood buffy coat cells has been used to detect significant infection in transplant recipients and AIDS patients (Spector et al. 1992; Boeckh et al. 1997; Cope et al. 1997; Razonable et al. 2002). More recent modifications of the PCR, including real-time PCR, that permit quantitation of viral burden has provided significant new information relevant to our understanding of CMV infections in the immunocompromised patient. Spector and colleagues were one of the first groups to demonstrate that the viral burden was predictive of the likelihood of an individual patient developing invasive disease (Spector et al. 1996). Several additional reports have also demonstrated the value of this approach (Cope et al. 1997; Emery et al. 2000; Zaia 2002). Real-time PCR with extended linear ranges of nucleic acid detection have permitted rapid and accurate measurement of virus burden in a variety of patient specimens.

Serological assays of antibody reactivity to CMV include nearly every imaginable technology. Detection of IgG is straightforward and seropositivity is evidence of infection only, and relative titers are usually of little clinical value. Seropositivity does not indicate active virus shedding, but should be taken as evidence of the potential infectivity of blood or organs from the individual. The measurement of CMV-specific IgM responses offers the possibility of distinguishing between acute infection and past infection (Stagno et al. 1985; Kropff et al. 1993). Unfortunately, this assay is often associated with low sensitivity and, occasionally, low specificity (Stagno et al. 1985; Landini 1993; Revello and Gerna 2002). Furthermore, the presence of rheumatoid factors may lead to false positive IgM results (Griffiths et al. 1982). Lastly, IgM antibodies are not present in the absence of IgG reactivity, so competition for antigenic sites between IgG and IgM antibodies is possible. IgM antibodies can persist for significant periods of time post acute infection and in some patients can persist for extended periods of time. The use of IgM reactivity to establish the chronicity of an infection is controversial and up to 40 percent of patients with past infection will have IgM anti-CMV antibodies (Revello and Gerna 2002) More recently, several laboratories have demonstrated that the measurement of anti-CMV IgG avidity can help distinguish between recent and past infection with CMV (Lazzarotto et al. 1998, 1999; Revello and Gerna 2002) This approach has been incorporated into an algorithm for the diagnosis and management of CMV infections during pregnancy (Bodeus et al. 2002; Revello and Gerna 2002).

Control

ANTIVIRAL THERAPY

Two agents with activity against CMV, ganciclovir and foscarnet are in current clinical use (Coen 1992). Both have significant toxicity, and resistant isolates have developed during treatment. Their use in AIDS patients is problematic since neither is virucidal and, when treatment is interrupted, virus replication resumes. Two additional compounds have recently been licensed for treatment of CMV infections in AIDS patients, specifically retinitis – Cidofovir and Fomivirsen.

Ganciclovir is a nucleoside analogue that inhibits chain elongation both by its activity as a chain terminator and through direct inhibition of the viral DNA polymerase (Sullivan et al. 1992, 1993). It is inactive until phosphorylated by the phosphotransferase activity of the UL97 ORF (Sullivan et al. 1992). It has been used to treat invasive infections in transplant recipients, retinitis and colitis in AIDS patients, and as part of a protocol to examine its efficacy in limiting sequelae in infants with congenital CMV infections (Meyers 1991; Spector et al. 1993) (Kimberlin et al. 2003). It also has some value as an antiviral prophylaxis in bone marrow transplant recipients (Goodrich et al. 1993; Seu et al. 1997; Ljungman 2001). Ganciclovir treatment causes primarily bone marrow toxicity with neutropenia as a major adverse effect. Ganciclovir is very poorly absorbed when given orally but dosing with sufficient drug can achieve similar serum levels as an intravenously given drug and similar therapeutic efficacy (Paya et al. 2002). However, its valine ester, valganciclovir, is readily absorbed and equivalent serum levels can be achieved with standard oral dosing regimens (Gane et al. 1997; Miller et al. 1997; Pescovitz et al. 2000; Curran and Noble 2001). This formulation of ganciclovir has been licensed for treatment of CMV infections in patients with AIDS following the demonstration of similar efficacy and safety profile of the oral valganciclovir when compared to intravenous ganciclovir for the treatment of CMV retinitis (Lalezari et al. 2002; Martin et al. 2002). Debate continues over the use of ganciclovir as

prophylaxis or as treatment when virus replication is detected (preemptive therapy). Both approaches have been shown to modify CMV disease in the post-transplant period (Emery 2001; Ljungman 2001; Singh 2001).

Foscarnet is an inhibitor of CMV DNA polymerases (Snoeck et al. 1993). It is also active against a wide variety of viral polymerases. This agent has been used extensively in AIDS patients and has demonstrated efficacy in CMV retinitis (Palestine et al. 1991). It causes significant renal toxicity, thus limiting its use under certain situations arising transplant recipients. This agent has been used extensively in patients who fail ganciclovir therapy.

Cidofovir and Fomivirsen are two compounds that were licensed for the treatment of CMV retinitis in AIDS patients. Cidofovir is a nucleoside analogue and inhibits CMV DNA replication in much the same manner as ganciclovir, with the exception that it does not require phosphorylation (De Clercq 1998). This latter property makes it useful for the treatment of patients who fail ganciclovir therapy secondary to mutations in the UL97 ORF (De Clercq 1998). Unfortunately, this agent has significant nephrotoxicity that has limited its use in almost all patient populations. Fomivirsen (ISIS 2922) is the first antisense RNA compound licensed for treatment of a human disease and is active against CMV in vivo and in vitro. The clinical experience with this compound is limited because of the changing natural history of opportunistic infections in AIDS patients which has followed HAART, but injection of this compound into the eye appears to be effective therapy for HCMV retinitis.

VACCINES

Past and recent epidemiological studies have argued that CMV is a vaccine-modifiable disease (Fowler et al. 1993; Fowler et al. 2003). Previous and current approaches for vaccine development have focused on replicating live viral vaccines. These have been referred to as attenuated viruses; however, as CMV does not exhibit identifiable virulence markers, this claim remains contentious. Vaccination of renal allograft recipients with one of these candidate viruses, the Towne strain of CMV, provided some evidence that it could induce protective responses (Plotkin et al. 1991). In a recent study, this vaccine failed to protect normal women from reinfection following exposure to children in a group care setting (Adler et al. 1995). Thus, it is unclear whether this vaccine in its current formulation is sufficiently immunogenic to induce protective immunity. Clinical trials are currently underway using a recombinant glycoprotein B combined with an adjuvant as an alternative approach. Although this vaccine appears to induce antibodies, including virus neutralizing antibodies, the durability of this response appears to be limited. It should be noted that recent studies have indicated that reinfection of previously immune women with genetically different strains of virus are relatively common in some populations, raising questions about the nature of protective immunity and therefore current vaccine strategies that attempt to recapitulate natural immunity (Boppana et al. 2001).

HUMAN HERPESVIRUSES 6 AND 7

HHV-6 and HHV-7 are two relatively recently described human viruses whose clinical importance remains to be fully defined. Isolation of HHV-6 from AIDS patients initially prompted speculation that it was an important cofactor in this disease (Salahuddin et al. 1986). This initial excitement was subsequently tempered by findings which demonstrated that infection with HHV-6 was common in all populations and that persistent shedding was characteristic of the biology of this virus. A second lymphotrophic betaherpesvirus, HHV-7, was isolated from $CD4^+$ T lymphocytes of normal individuals (Frenkel et al. 1990). Both viruses are acquired at an early age and seroprevalence is in excess of 60–80 percent by adulthood in most populations. Genetically, these viruses are closely related to CMV and exhibit genetic homology with CMV over an estimated two-thirds of their genomes (Lawrence et al. 1990; Inoue et al. 1993; Gompels et al. 1995; Megaw et al. 1998). A single serotype of HHV-7 has been described, whereas HHV-6 can be divided into two groups, A and B, based on biology, serological reactivity, and genetic composition (Ablashi et al. 1991; Schirmer et al. 1991). HHV-7 utilizes $CD4^+$ as its receptor whereas the receptor for HHV-6 is CD46, the same receptor utilized by measles virus (Lusso et al. 1994; Santoro et al. 1999). Subsequent studies have indicated that the CXC chemokine receptor 4 is not a coreceptor for HHV-7 as was initially proposed (Zhang et al. 2000).

Clinical manifestations

Recognizable clinical syndromes associated with HHV-6 and HHV-7 infection and confirmed by virological studies have been limited to primary infections in children. HHV-6 is the etiological agent of exanthem subitum (roseola), a common febrile illness of early childhood (Yamanishi et al. 1988). The clinical findings of this illness include high fevers (>39°C) of 3–5 days duration, nonspecific findings such as pharyngeal injection and diarrhea, and, perhaps most characteristically, rapid defervescence followed nearly coincidentally by the appearance of a generalized maculopapular rash (Okada et al. 1993; Asano et al. 1994; Hall et al. 1994; Suga et al. 1997; Caserta et al. 1998, 2001; Clark 2000). In contrast to this classical presentation, other studies have suggested that only about 10 percent of infants with primary HHV-6 infection exhibit the full spectrum

of exanthem subitum (Pruksananonda et al. 1992; Caserta et al. 2001). Interestingly, only the HHV-6B variant has been associated with exanthema subitum (Dewhurst et al. 1993). Symptoms including irritability, bulging anterior fontanelle, and seizures in a significant percentage of infants with roseola have been suggested as evidence of CNS infection (Kondo et al. 1993; Asano et al. 1994; Hall et al. 1994; Yoshikawa and Asano 2000). It has been suggested that primary infection with HHV-6 (strain B) and invasion of the CNS may predispose to the development and recurrence of febrile seizures (Kondo et al. 1993; Caserta et al. 1994; Yoshikawa and Asano 2000). Consistent with a direct role of HHV-6 in the development of seizures, other studies have documented the presence of HHV-6 nucleic acids in the cerebrospinal fluid (CSF) from patients with acute HHV-6 infection and also in the brain tissue from both immunocompetent and immunocompromised patients (Yoshikawa et al. 1992; Suga et al. 1993; Luppi et al. 1994; Ohashi et al. 2002). From these and other studies it appears that HHV-6 is neurotropic. HHV-6, and possibly HHV-7, are important causes of acute febrile illnesses in childhood, accounting for nearly 20 percent of hospital emergency room visits in the USA (Hall et al. 1994). Primary infection with HHV-7 is less well described but appears to cause a clinical syndrome very similar to that reported for HHV-6 with a possible difference being that primary HHV-7 infection occurs at an older age (Tanaka et al. 1994; Asano et al. 1995; Torigoe et al. 1995; Caserta et al. 1998). At least one report suggested that HHV-7 may be associated with the common childhood exanthem, pityriasis rosea, while other reports have failed to confirm this association (Drago et al. 1997; Kosuge et al. 2000). Clinically apparent infections in normal adults with either virus have been infrequently reported but, when diagnosed, resemble infectious mononucleosis (Steeper et al. 1990; Akashi et al. 1993). Reactivation of HHV-6, and possibly of HHV-7, often follows febrile illnesses, and reactivation of HHV-6 follows HHV-7 infection in vitro and in vivo (Kusuhara et al. 1991; Frenkel and Wyatt 1992; Asano et al. 1995). HHV-6 has also been associated with several rare disorders, including sinus histocytosis syndrome or Rosai–Dorfman disease (Foucar et al. 1990; Levine et al. 1992). It has been argued that HHV-6, and possibly HHV-6 infection, are associated with chronic fatigue syndrome; however, several studies have failed to demonstrate an increased incidence of infection with either of these viruses and this syndrome (Braun et al. 1995; Reeves et al. 2000). Clinical reports have linked HHV-6 with multiple sclerosis (MS) based on increased immunological responses to HHV-6, including HHV-6 specific IgG and IgM antibodies in patients with MS (Soldan et al. 2000). The experimental findings linking HHV-6 with the chronic demyelinating disease include: (1) detection of HHV-6 DNA by PCR in CSF from patients with MS at a higher frequency than controls; (2) detection of HHV-6 sequences in oligodendrocytes adjacent to plaques in the brain tissue from patients with MS but not control patients; (3) HHV-6-specific immunohistochemical staining of oligodendrocytes from plaques obtained from patients with MS but not control patients (Wilborn et al. 1994b; Challoner et al. 1995; Friedman et al. 1999; Akhyani et al. 2000; Knox et al. 2000; Tejada-Simon et al. 2002). In contrast, other studies have not reproduced these early findings (Hebart et al. 1997; Coates and Bell 1998; Mirandola et al. 1999). To date, definitive evidence of causality has not been presented but the association between HHV-6 and MS is intriguing and mandate additional studies to define this relationship.

Infection with HHV-6 can result in severe organ involvement, especially in immunocompromised hosts. It has been associated with a variety of specific clinical entities, including encephalitis, pneumonitis, hepatitis, and bone marrow dysfunction (Asano et al. 1990; Tajiri et al. 1990; Carrigan et al. 1991; Yoshikawa et al. 1992; Cone et al. 1993; Knox and Carrigan 1994; Singh 2000). This latter disorder may result from HHV-6 infection of hematopoietic progenitor cells, contributing to graft dysfunction in bone marrow transplant recipients (Knox and Carrigan 1992; Carrigan and Knox 1994). The proposed mechanisms responsible for bone marrow suppression in the bone marrow recipient have included both HHV-6 mediated cytolysis of progenitor cells and/or suppression of colony forming units through stimulation of cytokine production (Knox and Carrigan 1992; Drobyski et al. 1993). However, it should also be noted that 30–45 percent of hematopoietic cell allograft recipients develop HHV-6 viremia or HHV-6 DNAemia (Imbert-Marcille et al. 2000; Caserta et al. 2001; Yoshikawa et al. 2002; Boutolleau et al. 2003). Thus, it has been difficult to ascribe specific disease syndromes to HHV-6 infection/reactivation in these patients because the majority of allograft recipients with HHV-6 do not have symptoms attributable to this virus. The importance of HHV-6 in the solid organ allograft recipients is also unclear even though up to 50–60 percent of transplant recipients will reactivate the virus in the post-transplant period (Schmidt et al. 1996; Griffiths et al. 1999; Griffiths et al. 2000). Perhaps more interesting is the association between the reactivation of HHV-6 and CMV in the post-transplant period and the association between severe CMV disease and concomitant HHV-6 infection (Dockrell et al. 1997; Lowance et al. 1999; Humar et al. 2000; Kidd et al. 2000; DesJardin et al. 2001). As noted above, several studies have suggested that HHV-6 (or HHV-7) may play a role in graft dysfunction in the post-transplant period, including the graft rejection; however, these findings must be interpreted in the context of the use of potent immunosuppressive agents to maintain graft function and the reactivation of a variety of herpesviruses including HCMV (Okuno et al. 1990; Griffiths et al. 1999).

Although numerous case reports have linked HHV-6 infection to specific organ damage in the post-transplant period, it remains to be determined whether HHV-6 is a major cause of morbidity in this patient population because many of the patients in these studies were also infected with other agents such as HCMV. Alternatively, it has been argued that the success of antivirals in limiting post-transplant complications associated with CMV replication may also be explained by the activity of these compounds against HHV-6. Similarly, in patients with AIDS, HHV-6 and HHV-7 have been associated with a variety of clinical findings but their role, if any, in AIDS pathogenesis is unclear. In vitro studies have shown that HHV-6 can activate $CD4^+$ expression in $CD4^-$ cells raising the possibility that HHV-6 could increase the number of target cells for HIV infection in the HIV infected host (Lusso et al. 1991; Flamand et al. 1998). In contrast, other studies have suggested that HHV-6 infection can suppress HIV replication in dendritic cells and that HHV-6 can down-regulate the HIV coreceptor, CXC chemokine receptor 4 (CXCR4), in $CD4^+$ lymphocytes (Asada et al. 1999; Hasegawa et al. 2001). In clinical studies, there appears to be no quantitative relationship between the level of HHV-6 in peripheral blood mononuclear cell (PBMC) and $CD4^+$ lymphocyte counts in patients with AIDS, although HHV-6 dissemination appears to be more widespread in AIDS patients than controls (Fairfax et al. 1994; Clark et al. 1996; Fabio et al. 1997). In contrast, primary HHV-6 infection has been associated with more rapid progression of HIV disease in children (Kositanont et al. 1999). Whilst some investigators have suggested that HHV-6 and HHV-7 may function as cofactors in the development of the immune deficiency associated with HIV infection, there is currently little definitive information to support this hypothesis.

Epidemiology

The seroprevalence of HHV-6 increases rapidly through early childhood such that over 90 percent of infants in developed countries will be seropositive by the age of 2 years (Saxinger et al. 1988; Balachandra et al., 1989; Okuno et al. 1989). Serological reactivity in adults is also nearly universal. The vast majority of newborn infants are antibody positive, presumably because of transplacentally acquired maternal antibody, but become seronegative by 6 months of age (Balachandra et al. 1989; Yanagi et al. 1990). Approximately 10 percent of infants less than 1 month old can have detectable HHV-6 DNA in peripheral blood mononuclear cells, suggesting that in a minority of cases HHV-6 is acquired in the perinatal period (Hall et al. 1994). Because the rate of infection as measured by seroconversion increases rapidly during the interval between 6 and 12 months with a peak age of virus acquisition between 6–9 months of age, it has been hypothesized that maternal antibody may provide protective immunity early in infancy. In North America, HHV-6B is almost always associated with primary infection in infancy in contrast to the epidemiology in Zambia in which the majority of infections in infancy are associated with HHV-6A (Dewhurst et al. 1993; Kasolo et al. 1997). Co-infection with HHV-6A and 6B is common (Cone et al. 1996). In contrast, the seroprevalence of HHV-7 increases steadily throughout childhood and by 10 years of age almost all individuals are seropositive (Wyatt et al. 1991). Furthermore, the prevalence of HHV-7 antibody reactivity in different geographical locations is more variable than that reported for HHV-6 (Wyatt et al. 1991; Yoshikawa et al. 1993; Ablashi et al. 1994). Serological reactivity for HHV-6 does not prevent infection with HHV-7 as evidenced by the later age of acquisition of HHV-7 as compared to HHV-6 and the frequent occurrence of HHV-6 and HHV-7 infection in older patients. Reactivation of HHV-6 occurs in about 40 percent of seropositive women during pregnancy and HHV-6 DNA was reported in about 1 percent of cord blood (Dahl et al. 1999). Other reports have suggested that intrauterine transmission of either virus is exceedingly rare (Balachandra et al. 1989; Yanagi et al. 1990; Aubin et al. 1992). Furthermore, HHV-6 can be found in the cervix but perinatal transmission appears infrequent (Okuno et al. 1989; Leach et al. 1993).

HHV-6 and HHV-7 can be readily isolated in the early post-transplant period from both solid organ and bone marrow allograft recipients. Increases in serological responses and viremia, as measured by culture and/or PCR, are commonly detected in up to 80 percent of transplant recipients in the first 3 months after transplantation (Okuno et al. 1990; Wilborn et al. 1994b; Chan et al. 1997; Imbert-Marcille et al. 2000; Yoshikawa et al. 2002; Boutolleau et al. 2003). More recent studies have indicated that HHV-7 was isolated in the post-transplant period as often as HHV-6 in HCMV-infected patients and when HHV-7 DNA was assayed by PCR, HHV-7 was detected more frequently than in HHV-6 in the post-transplant period (Kidd et al. 2000; Mendez et al. 2001; Lautenschlager et al. 2002; Boutolleau et al. 2003). In addition, HHV-6 antigens can be detected in up to 60 percent of renal allograft biopsies, a finding consistent with the proposed role of HHV-6 in graft rejection (Hoshino et al. 1995; Griffiths et al. 1999). However, as noted previously, the contribution of HHV-6 (and presumably HHV-7) to post-transplant morbidity and mortality remains uncertain and recent studies have demonstrated a significantly lower incidence of HHV-6 reactivation than HCMV in heart-lung transplant recipients (Michaelides et al. 2002). Furthermore, HHV-6 DNA could be detected in lung tissue in patients, both bone marrow transplant recipients and controls, who were HHV-6 seropositive (Cone et al. 1993). Similarly, the rate of HHV-7 detection in a group of stem cell

transplant recipients was nearly equivalent in peripheral blood specimens analyzed pre- and post-transplant (Boutolleau et al. 2003). Thus, it remains difficult to assign causality to HHV-6 and/or HHV-7 in post-transplant syndromes such as pneumonitis because of the near universal recovery of HHV-6 and the frequent presence of other agents such as HCMV or adenovirus in the same biopsy tissue from transplant patients.

Sources of virus include exposure to saliva, genital secretions, and PBMC (Levy et al. 1990a; Wyatt and Frenkel 1992; Black et al. 1993; Cone et al. 1994; Leach et al. 1994). Although breast milk would seem to be a likely source of HHV-6 and HHV-7, current understanding of the natural history of these infections suggests that breast milk is not a common mode of transmission. There appear to be no significant differences in the rate or age of acquisition of HHV-6 between breast-fed and nonbreast-fed infants (Takahashi et al. 1988). This epidemiologic observation is consistent with at least one study indicating that HHV-6 could not be detected in breast milk (Dunne and Jevon 1993). Limited studies in families have suggested that exposure to respiratory secretions is the most likely mode of intrafamilial spread of HHV-6 (Mukai et al. 1994). HHV-6 and HHV-7 are persistently excreted in the saliva following primary infection and in individuals with past infections, although it appears that HHV-7 is more frequently detected in saliva than HHV-6 (Levy et al. 1990b; Wyatt and Frenkel 1992; Black et al. 1993; Mukai et al. 1994; Kidd et al. 1996; Lucht et al. 1998). HHV-7 has been isolated from saliva in 60–80 percent of seropositive adults (Black et al. 1993; Hidaka et al. 1993; Black and Pellett 1999). Both viruses can be detected in PBMC from seropositive individuals using PCR, suggesting that blood may be an important source of virus transmission in hospitalized patients (Cone et al. 1994; Kidd et al. 1996).

The biological behavior of the virus in tissue culture, including such characteristics as the cellular tropism of the different HHV-6 variants and the virus yield from cord blood lymphocytes, initially suggested the possibility of variants of HHV-6 (Wyatt et al. 1990; Ablashi et al. 1993; Gompels et al. 1993). Additional studies have documented the presence of two genetically and serologically distinct variants of HHV-6, type A and type B (Ablashi et al. 1991; Schirmer et al. 1991). Comparison of the genomes from prototypic HHV-6A and HHV-6B viruses have revealed identical nucleotide sequence over 75–97 percent of the genome, depending on the region of the genome analyzed (Gompels et al. 1995). Overall, there is approximately 95 percent identity for most genes found in conserved gene blocks, but only 75 percent conservation in genes found in HHV-6 and not in other betaherpesviruses. Interestingly, recombination between variants occurs uncommonly, if at all. These variants are also associated with specific diseases as illustrated by the finding that over 95 percent of cases of roseola in the USA are caused by group B viruses (Dewhurst et al. 1993). Furthermore, HHV-6B, but not HHV-6A, has been shown to replicate in salivary glands as evidenced by its isolation from saliva (Harnett et al. 1990; Levy et al. 1990a; French et al. 1999). Studies from several different transplant centers have also documented that the B variant is more frequently associated with infections in the post-transplant period (Frenkel et al. 1994; Wilborn et al. 1994a; Boutolleau et al. 2003). The basis for the association between the B variant of HHV-6 and specific clinical syndromes remains unexplained. Together, these findings have been used by some investigators to suggest that HHV-6a and HHV-6b are distinct betaherpesviruses and not merely variants of one another.

Pathogenesis

Little is known about the pathogenesis of HHV-6 and HHV-7 infections; however, it must be assumed that, as the majority of infections are subclinical, normal host responses can effectively limit virus-induced cellular damage. In addition, there are no consistent and specific histopathological changes in target organs that suggest direct virus mediated cytopathology (Kurata et al. 1990). Because the severity of roseola can be related to the level of HHV-6 viremia, viral load may be an important determinant of this disease, and presumably of organ damage (Asano et al. 1991). Recent findings in transplant patients infected with HHV-6 also argue for a correlation between virus load and clinical disease (Ljungman 2002; Zerr et al. 2002; Boutolleau et al. 2003) The pathogenetic mechanism(s) leading to the clinical syndrome of roseola are unknown, but the lymphocyte tropism of the virus suggests that cytokines could contribute to the symptoms associated with this infection. HHV-6 infection of lymphocytes induces production of a variety of lymphokines, including TNF, IL-1β, IL-10, IL-12, and interferons (Flamand et al. 1991; Flamand et al. 1996; Campadelli-Fiume et al. 1999). Furthermore, HHV-6 encodes at least two chemokine receptor (UL12, UL51), of which at least one, UL12, is a functional receptor (Isegawa et al. 1999). Together with its lymphotropic behavior, it is almost certain that many of the clinical findings associated with primary infection with HHV-6 can be related to host derived inflammatory responses and not virus-induced cytopathology. Using techniques that detect viral nucleic acids or viral antigens in the absence of histopathological changes, HHV-6 has been demonstrated in alveolar macrophages from transplant patients with pneumonitis, hepatocytes from patients with hepatitis, and brain tissue from patients with encephalitis (Asano et al. 1990; Carrigan et al. 1991; Carrigan and Knox 1994; Cone et al. 1994). It has also been suggested that HHV-6 infection in bone marrow transplant recipients may contribute to more severe graft-versus-host disease (Wilborn et al. 1994a).

As noted previously, the possible role of HHV-6 in the pathogenesis of end organ diseases in transplant recipients is controversial because of the presence of other opportunistic pathogens and the near universal presence of HHV-6 and HHV-7 in the adult population (Cone et al. 1994, 1999; Black and Pellett 1999).

If the relationship between HHV-6 infection and disease can be considered to be incompletely defined, the relationship between specific syndromes and clinical disease and HHV-7 infection is unknown. HHV-7 infection is associated with reactivation of HHV-6 and, therefore, the assignment of the relative contribution of each virus to a clinical illness is impossible. However, the later age of HHV-7 acquisition and the lack of definable syndromes associated with HHV-7 infection suggest that its potential to cause disease in the normal host is limited. In the immunocompromised host however, HHV-7 has been proposed to be an important cofactor in the severity of disease associated with human cytomegalovirus infection in the post-transplant period (Kidd et al. 2000; Tong et al. 2000; Mendez et al. 2001). An interesting finding in these studies was that disease association between these viruses was only demonstrated when the quantity of virus in blood was measured and not just the qualitative presence or absence of either virus. Thus, it would appear that clinically significant interactions between these viruses require increased viral loads, a feature unique to patients with more significant immune dysfunction. In vitro, HHV-7 has been shown to induce $CD4^+$ lymphocyte death by both direct cytolysis and apoptosis, raising the possibility that active HHV-7 replication could contribute to the immune suppression in the post-transplant period (Secchiero et al. 1997). Perhaps this or a related mechanism could explain the role of HHV-7 in severe HCMV infection in the post-transplant period.

The association of HHV-6 infection with central nervous dysfunction, most commonly manifest as seizure activity, is particularly intriguing. Roseola is frequently associated with irritability and a bulging anterior fontanelle, two nonspecific findings of CNS involvement in this childhood infection. Case reports have provided evidence of CNS infection by HHV-6, including detection of HHV-6 nucleic acids in the CSF and in brain tissue from fatal cases (Asano et al. 1990; Ishiguro et al. 1990; Yoshikawa et al. 1992; Yoshikawa and Asano 2000). Virus could also be demonstrated in endothelial cells in the brain of fatal cases of HHV-6 encephalitis, suggesting the possibility of vasculitis as a cause for CNS disease (Yoshikawa and Asano 2000). HHV-6 has also been detected in a variety of cell types in brain tissue from HHV-6 infected patients with AIDS, including astrocytes, oligodendrocytes, microglia, and neurons (Ohashi et al. 2002). Other studies have also demonstrated, by PCR, viral nucleic acid in the CSF (Kondo et al. 1993; Suga et al. 1993; Achim et al. 1994; Caserta et al. 1994; Wilborn et al. 1994a). Interestingly, in several of these studies, including the largest in terms of number of patients, virus could not be isolated from the CSF (Hall et al. 1994). Because of the propensity of HHV-6 to reactivate after a febrile illness, including HHV-7 infection, the demonstration of viral nucleic acid in the CSF without additional evidence of tissue invasion or local replication of virus, suggests only an association between HHV-6 and CNS dysfunction and not causality. Although HHV-6 nucleic acids have been detected in normal hosts with encephalitis and compelling arguments can be made for this virus as a cause of sporadic encephalitis, definitive evidence for a direct role in childhood seizures associated with primary infection is lacking (Yoshikawa et al. 1991). Similarly, primary HHV-7 infection has been associated with the development of seizure activity (Torigoe et al. 1995; Caserta et al. 1998). It has been suggested that primary HHV-7 infection is more frequently associated with seizures in young infants, but little definitive evidence is available to support a direct role for this virus in CNS dysfunction in the normal host.

Since their discovery, HHV-6 and HHV-7 have been suspected to have a role in the pathogenesis of HIV infection. Several biological characteristics support this suspicion. These include: (1) growth in T lymphocytes in vivo and in vitro, (2) the use of CD4 as a cellular receptor by HHV-7, (3) induction of CD4 expression after infection of lymphocytes, and (4) transactivation of the HIV long terminal repeat (Ensoli et al. 1989; Takahashi et al. 1989; Ablashi et al. 1991; Lusso et al. 1991, 1994; Martin et al. 1991; Kashanchi et al. 1994; Wang et al. 1994; Zhou et al. 1994; Lusso and Gallo 1995). However, epidemiological studies have provided little definitive evidence suggesting that either HHV-6 or HHV-7 plays an important role in the progression to AIDS in HIV-infected individuals (Fox et al. 1988; Spira et al. 1990; Fairfax et al. 1994; Lusso et al. 1994). Furthermore, HHV-6 has been shown to inhibit the replication of HIV in vitro (Levy et al. 1990b). In contrast to this early finding, other studies have suggested that co-infection of HIV-infected cells with lower inocula of HHV-6 may actually lead to enhanced HIV replication (Lusso et al. 1994). Thus, it remains to be determined whether co-infection with HHV-6 or HHV-7 contributes to the progression of HIV infections.

Immunity

Immunological responses in normal hosts are sufficient to limit the replication and spread of HHV-6 and HHV-7 as evidenced by the infrequent development of symptomatic infection and the self-limited nature of the infection. The natural history of HHV-6 infection suggests that passively acquired immunity in early infancy is sufficient to prevent infection. It is unclear what role maternal immunity plays in the natural history of HHV-7. Host immune responses that limit reactivation in

normal hosts and curtail invasive infection in immunocompromised hosts are unknown, but, if analogous to other herpesvirus infections, are probably virus-specific cellular responses. The frequent shedding of both viruses in patients undergoing immunosuppressive therapy or individuals with HIV is consistent with a critical role for cellular immunological effector functions in limiting virus replication.

CELLULAR IMMUNE RESPONSES

HHV-6 infection can induce the production of antiviral cytokines, including interferons. NK cell activity and interferon-α levels have also been reported to be elevated in acute HHV-6 infection and in vitro studies have suggested that these activities may play a role in controlling HHV-6 in replication in vivo (Kikuta et al. 1990; Takahashi et al. 1992). Analysis of $CD4^+$ lymphocyte clones derived from infected individuals has revealed that, although most were specific for HHV-6, about 10 percent responded to both HHV-6 and HHV-7 and an even smaller number were cross-reactive with HHV-6, HHV-7, and CMV (Yasukawa et al. 1993). Group A and B variants of HHV-6 could be distinguished by reactivity of 7 percent of the clones. MHC-restricted cytotoxic T cell clones specific for HHV-6 infected cells have also been isolated (Yakushijin et al. 1992). The antigen specificity of the cellular responses against HHV-6 and HHV-7 remains to be defined.

ANTIBODY RESPONSES

The serological responses to HHV-6 and HHV-7 are extraordinarily complex. In the case of HHV-6, IgM antibodies specific for HHV-6 appear 5–7 days after the onset of clinical symptoms and peak around 2–3 weeks (Suga et al. 1993). The IgG antibody response to HHV-6 can first be detected 7–10 days after resolution of clinical symptoms and remain detectable for the life of the host (Ueda et al. 1989). The serological reactivity to HHV-7 appears to have similar kinetics (Yoshida et al. 2002). A large number of virus-encoded proteins are recognized by convalescent sera, but to date the antibody components of protective immunity have not been defined. Immune precipitation of radiolabelled virus-infected cell proteins with convalescent serum revealed over 20 different proteins could be precipitated (Balachandran et al. 1991). At least five glycoproteins were precipitated from infected cells (Balachandran et al. 1991). More recent studies have identified specific viral proteins that are targets of antibody responses including the gB and gH HHV-6 homologues (Ellinger et al. 1993; Liu et al. 1993; Qian et al. 1993). In addition, the major glycoprotein complex of the A variant of HHV-6, gp82-105, has been shown to be a target of neutralizing antibodies (Pfeiffer et al. 1993). A major antigenic protein of HHV-6, designated p100, is the homologue of CMV pp150 (UL32) and probably represents a dominant target of virus-specific antibodies (Neipel et al. 1992). Cross-reactivity exists between conserved structural proteins such as the major capsid protein and the nonstructural protein CD41 (homologue of CMV pp50 (UL44)) (Loh et al. 1994). Interestingly, cross-reactivity has also been shown between the major envelope glycoprotein of CMV (gB) and HHV-6 (Adler et al. 1993). The serological response to HHV-7 is equally complex, with over 15 radiolabelled infected cell proteins demonstrable by immune precipitation (Foa-Tomasi et al. 1994). Several HHV-7 encoded proteins have been shown to be recognized by immune human serum, including an 80 kDa glycoprotein which probably represents the HHV-7 homologue of gH, the gB homologue, an immunogenic tegument protein of estimated mass of 85 kDa (U14), and p86 (U11) (Foa-Tomasi et al. 1996; Nakagawa et al. 1997; Stefan et al. 1997; Stefan et al. 1999; Franti et al. 2002). Antigenic cross-reactivity between HHV-6 and HHV-7 encoded proteins has also been demonstrated and likely is an explanation for the confusion that surrounds the interpretation of seroprevalence studies (Foa-Tomasi et al. 1994, 1996; Black and Pellett 1999). Currently, routine serological assays cannot distinguish between the two variants of HHV-6.

Diagnosis

The diagnosis of HHV-6 and/or HHV-7 infection requires the detection of virus, viral antigens or viral nucleic acids in an appropriate specimen from a patient with a clinical syndrome compatible with infection by either of these viruses. HHV-6 and HHV-7 can be recovered with a reasonable degree of success from children in the early phase of exanthem subitum by cocultivation of peripheral blood lymphocytes with umbilical cord lymphocytes. Both HHV-6 and HHV-7 can also be recovered from saliva, although less consistently than from lymphocytes. Other cells suitable for virus isolation include phytohemagglutinin-stimulated PBMC. Cell lines such as HSB2, Sup T1, and Molt-3 have been used to propagate HHV-6, although tropism for specific cell lines may vary (Osman et al. 1993). Isolation of HHV-6 remains a reliable method for the diagnosis of active HHV-6 infection (Carrigan and Knox 2000). Cell lines permissive for HHV-7 have not been described. Viral antigens within infected cells can be readily detected by immunological assays that incorporate HHV-6 or HHV-7 specific monoclonal antibodies (Yamamoto et al. 1990; Ablashi et al. 1993; Parker and Weber 1993). Monoclonal antibodies can be used to distinguish between HHV-6A and HHV-6B (Foa-Tomasi et al. 1994). Perhaps the most useful assays for HHV-6 and HHV-7 are PCR amplification of specific regions of the viruses. These can be carried out on a number different clinical specimens, including PBMC, saliva, and plasma. The judicious selection of primers allows HHV-7 and the two variants of HHV-6 to be distinguished from one another

(Aubin et al. 1994; Yamamoto et al. 1994; Secchiero et al. 1995). Quantitative PCR assays aid in distinguishing between asymptomatic shedding of HHV-6 and/or HHV-7 and invasive disease (Clark et al. 1996; Kidd et al. 1996; Kidd et al. 2000). Finally, an antigenemia assay similar to the widely employed HCMV antigenemia assay has been used to identify active HHV-6 infection in transplant recipients (Lautenschlager et al. 2002).

Serological assays have yet to be rigorously standardized and, because of significant cross-reactivity between HHV-6 variants and HHV-7, confirmatory testing including absorption with heterologous viral antigens should be considered (Braun et al. 1995; Ward et al. 2001). Antibody avidity assays have been reported that can distinguish between primary HHV-6 and HHV-7 infections (Ward et al. 2001). With the identification of specific viral proteins and their corresponding ORFs, recombinant antigen-based serological assays could overcome issues of cross-reactivity and the high seroprevalence rates in the population.

Control

Although ganciclovir and foscarnet are virustatic for both HHV-6 and HHV-7, current in vitro testing of antiviral susceptibility of these viruses is poorly standardized (Williams 1992). As an example, reports have indicated that some strains of HHV-6 may be relatively resistant to ganciclovir whereas others are susceptible (Akesson-Johansson et al. 1990). Therefore, it is unclear whether adequate in vivo concentrations of drug can be achieved; however, a study in hemapoietic stem cell transplants suggested that ganciclovir treatment resulted in a significant fall in HHV-6 viral burden (Zerr et al. 2002). The HCMV UL97 homologue in HHV-6 (UL69) has been assigned to orf UL69 based on its expression in a recombinant insect virus and its capacity to phosphorylate ganciclovir (Ansari and Emery 1999). Consistent with this finding, some isolates have exhibited drug sensitivities comparable to those reported for CMV. Clinical indications for antiviral therapy will most likely be limited to immunocompromised patients with significant end organ disease; end organ disease such as pneumonitis, in which biopsy tissue could be used to confirm a clinical diagnosis, could be one group that may benefit from antiviral therapy.

PROPERTIES OF THE VIRUS

DISCOVERY OF THE VIRUS

Kaposi's sarcoma (KS), first described in 1872 by the Viennese dermatologist Moriz Kaposi (Kaposi 1872) in the classic form, has since been known as a peculiar semi-malignant tumor of the skin. It afflicted mainly elderly men of southern or east European descent. The frequent appearance of an unusually aggressive form of KS in young homosexual men was one of the observations marking the advent of the acquired immune deficiency syndrome (AIDS) epidemic in developed countries (Friedman Kien et al. 1982). The uneven distribution of KS amongst different transmission groups for the human immunodeficiency virus (HIV) resulted in the hypothesis that an environmental factor or a transmissible agent other than HIV is involved in KS pathogenesis (Beral et al. 1990). Most notably, whereas more than 20 percent of homosexual and bisexual AIDS patients developed KS, only 1 percent of age- and sex-matched men with hemophilia suffered from this uncommon tumor, suggesting – amongst others – transmission of a KS-related virus by sexual practice. Application of representational difference analysis (Lisitsyn et al. 1993) a polymerase chain reaction (PCR)-based method, resulted in the identification of two short DNA fragments from a new herpesvirus (Chang et al. 1994). The virus is now termed human herpesvirus 8 (HHV-8) or Kaposi's sarcoma-associated herpesvirus (KSHV). The latter name reflects a finding that was previously claimed in the paper describing the identification of HHV-8 (Chang et al. 1994). HHV-8 DNA is regularly found in KS tissues, but not in uninvolved skin or the vast majority of other malignancies. These include most solid tumors as well as various lymphomas. The few notable exceptions identified to date are two types of B-cell lymphoma or lymphoproliferative lesion, namely primary effusion lymphoma (PEL), and the plasma-cell-rich variant of multifocal Castleman disease (MCD). Similar to KS, HHV-8 DNA is almost always present in PEL and in the majority of MCD cases, suggesting a causative role of the virus in oncogenesis.

CLASSIFICATION

HHV-8 is the first and only known human member of the genus *Rhadinovirus* or γ_2-herpesvirus. This classification is based on DNA homology between the HHV-8 genome and that of other γ_2-herpesviruses (McGeoch 2001).

Related primate rhadinoviruses

Rhadinoviruses have been known for many years as animal viruses infecting primates (Fleckenstein and Desrosiers 1982; Fleckenstein et al. 1978), rodents and ungulates (Table 1). These viruses are usually widespread and generally apathogenic in their natural host. However, upon infection of closely related but distinct species, several animal rhadinoviruses are known to induce diseases, such as malignant catarrhal fever in

Table 1 *The genus* Rhadinovirus

Virus type	Natural host	Pathogenicity in natural host	Foreign hosts	Pathogenic properties in foreign hosts
Human herpesvirus type 8	Human	Kaposi's sarcoma, MCD, PEL		
Herpesvirus saimiri	Squirrel monkey		Marmosets, etc.	Polyclonal malignant T-cell lymphomas
Herpesvirus ateles	Spider monkey		Marmosets, etc.	Polyclonal malignant T-cell lymphomas
Rhesus monkey rhadinovirus	Rhesus monkey	Lymphadenopathy		
Retroperitoneal fibromatosis-associated herpesvirus of *Macaca mulatta*/*Macaca nemestrina*	*Macaca mulatta*/*Macaca nemestrina*	Retroperitoneal fibromatosis?		?
Pan troglotydes rhadinovirus-1	Chimpanzee	?	?	?
Gorilla rhadinovirus-1	Gorilla	?	?	?
Alcelaphine herpesvirus type 1	Wildebeest		Cattle, buffalo	Malignant catarrhal fever
Ovine herpesvirus type 2	Sheep		Cattle	Malignant catarrhal fever
Bovine herpesvirus type 4	Cattle			
Equine herpesvirus type 2	Horse	Transient immunosuppression in foals		
Herpesvirus sylvilagus	Cottontail rabbit	(Benign) lymphoproliferative syndrome		
Murine herpesvirus-68	Wood mouse		Mouse	Benign splenomegaly

Various primate- and nonprimate rhadinoviruses, their natural host and, if applicable, foreign hosts as well as pathogenic properties in a foreign host are given. Please note that in the case of Pan troglotydes rhadinovirus-1, Gorilla rhadinovirus-1, and the retroperitoneal fibromatosis-associated rhadinoviruses, the complete virus has not thus far been isolated. Only fragments from the DNA polymerase gene could be amplified and sequenced using a degenerate PCR approach.

cattle or T-cell lymphoma in certain neotropical primates (Table 1).

HERPESVIRUS SAIMIRI

Herpesvirus saimiri is a well-studied example of this group (Fickenscher and Fleckenstein 2001). Herpesvirus saimiri is apathogenic in its natural host, the squirrel monkey *Saimiri sciureus*. However, closely related new world primates like the marmoset succumb with highly malignant T-cell proliferation upon experimental infection with herpesvirus saimiri. Certain strains of herpesvirus saimiri effectively transform cultured human T-lymphocytes (Biesinger et al. 1992). The genes responsible for growth transformation are essentially known, and nontransforming deletion mutants have been generated. In contrast to HHV-8, the closely related herpesvirus saimiri can be effectively propagated in cell culture. It has thus been used as a model system for HHV-8 (Lee et al. 1998; Jung et al. 1999).

RHESUS RHADINOVIRUS

The discovery of HHV-8/KSHV as the first human rhadinovirus in 1994 stimulated the search for rhadinoviruses in other Old World primates. Serological studies using HHV-8-derived antigens indicated that a herpesvirus closely related to HHV-8 may exist in rhesus monkeys. Co-cultivation of lymphocytes from seropositive rhesus monkeys with fibroblasts resulted in the isolation of a novel rhesus rhadinovirus (RRV) (Desrosiers et al. 1997). The complete genomic sequences from two independent RRV isolates are available (Alexander et al. 2000; Searles et al. 1999). This revealed that RRV is indeed more closely related to HHV-8 than the prototypic rhadinovirus herpesvirus saimiri (HVS). The genomes of RRV and HHV-8 are essentially colinear. RRV contains (at least) 84 genes, 80 of which are homologous to genes found in HHV-8. Thus, at this point in time RRV is the closest known relative of HHV-8 which has been fully sequenced. RRV seems to be very widespread amongst monkeys kept in captivity. No clear disease association has been identified for RRV in otherwise healthy macaques as yet. However, inoculation with RRV resulted in the development of a multifocal lymphoproliferative disease when rhesus macaques were immunosuppressed as a consequence of infection with simian immunodeficiency virus (Alexander et al. 2000; Wong et al. 1999). In contrast to HHV-8, RRV can be readily propagated in cell culture.

RETROPERITONEAL FIBROSIS RHADINOVIRUSES

In a second approach targeted at the identification of Old World primate rhadinoviruses, Rose and co-workers studied tissue specimens from simian retroperitoneal fibromatosis (RF). RF has been identified as an infrequent disease syndrome occurring in immunosuppressed macaques (Giddens et al. 1985). RF lesions consist of an aggressively proliferating fibrous tissue with a high degree of vascularization and thus remotely resemble KS. Transmission studies indicated that an infectious agent may be involved in RF pathogenesis (Giddens et al. 1985). By using a degenerated PCR technique, fragments of a herpesvirus DNA polymerase gene were identified in RF tissues from two macaque species, *Macaca nemestrina* and *Macaca mulatta* (Rose et al. 1997). Sequence comparisons indicated that at least the DNA polymerase genes of these two novel rhadinoviruses, tentatively termed RFHVMm and RFHVMn, are more closely related to KSHV than the DNA polymerase genes of RRV. However, attempts to isolate these viruses on cultured cells or to obtain additional sequence information have not been successful so far.

HHV-8 VIRION MORPHOLOGY

The morphology of the enveloped HHV-8 virion is comparable to other herpesviruses. The three-dimensional structure of the human herpesvirus 8 capsid has been determined by cryo-electronmicroscopy using viral particles produced from cultured primary effusion lymphoma (PEL) cells at a resolution of 22–24 Å (Trus et al. 2001; Wu et al. 2000). The HHV-8 capsid is similar to those of other herpesviruses, especially herpes simplex virus-1. The icosahedral capsid shell is composed of 162 capsomers (12 pentons, 150 hexons).

MOLECULAR BIOLOGY

Genome structure

The HHV-8 genome is a linear, double-stranded DNA of approximately 160 kbp and has the overall structure typical for rhadinoviruses (Figure 1). A complete rhadinovirus genome is usually termed M genome, as it is of inter*m*ediate density (M-DNA). The γ_2-herpesviruses were termed rhadinoviruses utilizing the ancient Greek word for fragile, because this M-DNA tends to split into two fractions of DNA molecules with highly different density, the L-DNA containing genes (low density, low G+C content) and the terminal repetitive H-DNA (high density, high G+C content). The latter is, as far as currently known, without coding capacity. The almost complete nucleotide sequence of HHV-8 was determined from both a PEL cell line (Russo et al. 1996) and from a KS biopsy specimen (Neipel et al. 1997b). The central low-GC (53.3 percent G+C, L-DNA) coding fragment is flanked by numerous tandem repeats of high GC content (84.5 percent G+C, H-DNA). The L-DNA contains at least 89 open reading frames, 67 of which have homologues in the closely related γ_2-herpesvirus prototype herpesvirus saimiri (Figure 1). The overall amino acid sequence identity of these 67 HHV-8 reading frames to homologues identified in herpesvirus saimiri ranges from

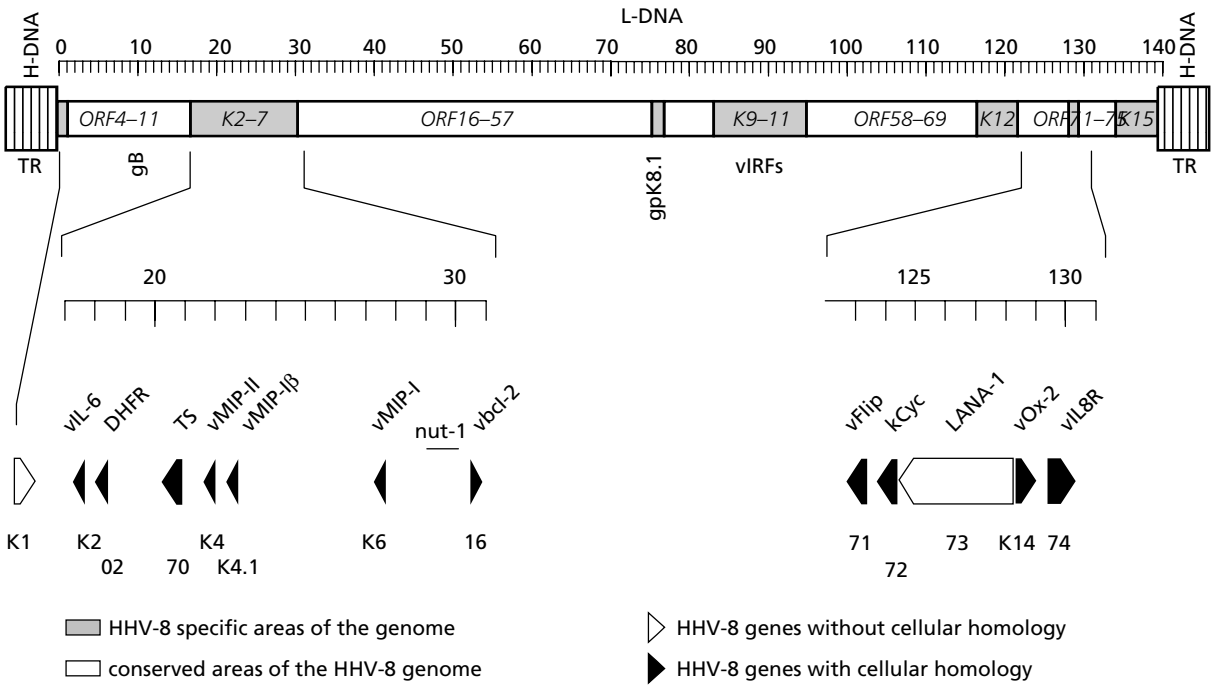

Figure 1 *Specific traits of the HHV-8 genome in a linear representation. A central low-GC (53.3 percent G+C,* L-DNA*) coding fragment is flanked by numerous tandem repeats (TR) of high G+C content (84.5 percent G+C,* H-DNA*). The L-DNA contains at least 89 open reading frames, most of which have homologues in other herpesviruses. These blocks of conserved herpesvirus genes are symbolized by open boxes in the upper half of the figure. They are interrupted by nonconserved areas shown in light gray. Most of the HHV-8 genes thought to be directly involved in pathogenesis – either by direct growth transformation or through paraendocrine mechanisms – are located within these HHV-8-specific areas. They are shown enlarged in the lower part of the figure. Black arrows indicate HHV-8 genes with homology to cellular genes. HHV-8 genes without known homology to cellular genes are shown as open arrows. HHV-8 reading frames that share homology with herpesvirus saimiri were assigned the corresponding reading frame numbers following the nomenclature by Albrecht et al. (1992).* HHV-8 *genes without recognizable homologues in herpesvirus saimiri were numbered separately and given the prefix K (K1–K15) (Russo et al. 1996). DHFR, dihydrofolate reductase; gB, glycoprotein B; gpK8.1, glycoprotein K8.1; kCyc, HHV-8 cyclin-D homologue; nut-1, nuclear tRNA-like transcript; TS, thymidylate syntase; vbcl-2, viral bcl-2; vFlip, viral FLICE inhibitory protein; vIL-6, viral interleukin-6; vIL8R, viral interleukin-8 receptor; vIRFs, viral interferon response factor homologue; vMIP-I/II, viral macrophage inflammatory protein-I/II; vMIP-1β, open reading frame with homology to macrophage inflammatory protein-1β or macrophage chemoattractant protein; vOx-2, viral Ox-2 homologous gene.*

22.4 to 66 percent (average, 42 percent). Conserved genes are usually found in a comparable genomic position and orientation. Thus, HHV-8 genes that share homology with herpesvirus saimiri are numbered from left to right according to their position on the herpesvirus saimiri genome. Open reading frames which do not share recognizable amino acid homology with genes in herpesvirus saimiri are numbered with the prefix K (Figure 1). To date, 19 genes have been identified which are not clearly homologous to genes identified in herpesvirus saimiri (K1–K15, K4.1, K4.2, K8.1, K10.5). Frequently, these 'K'-genes are strikingly homologous to known cellular genes. They code for proteins interfering with the immune system, for enzymes of the nucleotide metabolism, and for putative regulators of cell growth (Figure 1).

Virus-coded proteins

Human herpesvirus-8 DNA is present in the vast majority of KS spindle cells and primary effusion lymphoma B cells. The virus establishes a latent infection in these cells: virus progeny is not produced and only a limited set of viral genes is expressed. Whereas the HHV-8 genome is quickly lost from cultured KS spindle cells, cultured PEL cells maintain the viral genome. The full lytic program is spontaneously activated in only a few cells of a PEL culture (<1 percent). However, lytic replication can be induced in up to 5–40 percent of PEL cells by the addition of phorbol esters and/or sodium butyrate (Renne et al. 1996). Genes expressed during the HHV-8 lytic replication cycle have been essentially studied on cultured PEL cells treated with such agents. Most of these genes have pronounced homology to those of other herpesviruses. Although de novo infection of cultured cells has not been studied extensively, HHV-8 lytic genes have been divided into immediate–early, early, and late depending on their temporal expression following reactivation from latently infected, cultured cells: (1) transcription of immediate–early genes is inducible by TPA/butyrate even in the presence of agents blocking protein biosynthesis; (2)

expression of early genes requires the presence of immediate–early protein, but takes place in the absence of DNA replication; (3) transcription of late viral genes does not take place when DNA replication is inhibited. This temporal gene expression pattern where one set of genes is activated by genes expressed earlier during the lytic cycle was initially defined using herpes simplex virus and de novo infection of cultured cells. The situation in HHV-8 is different so far, as most data on temporal gene regulation were derived from latently infected PEL cells where lytic replication of the virus is activated by phorbol esters or sodium butyrate. In an alternative classification, HHV-8 transcripts were divided into three groups according to their inducibility by tetradecanoylphorbol acetate (TPA) (Sarid et al. 1998). Class I genes were transcribed constitutively, i.e. under standard growth conditions without the addition of stimulating agents like TPA; their expression did not increase when the lytic cycle was induced by TPA. Class I genes were mapped to a region close to the right end of the L-DNA encoding ORF73 (latent nuclear antigen 1, LANA), ORF72 (viral cyclin-D, vCyclin) and ORF71 (viral flice inhibitory protein, vFLIP). They constitute bona fide latently expressed genes. Class II transcripts were detectable without TPA treatment, but clearly induced to higher transcription by the addition of TPA. Essentially, immediate–early and early genes belong to this intermediate class. Until today, three immediate–early transcripts have been identified in HHV-8: ORF4.2, ORF45, and ORF50 (Zhu et al. 1999). Class III transcripts were not detectable without stimulation of cultured PEL cells by TPA or butyrate. Essentially, they comprise the late, structural proteins of HHV-8.

Lytic regulatory proteins

The lytic regulatory proteins of HHV-8 studied so far include open reading frame 50, also termed replication and transcription activator (RTA), Lyta (lytic transactivator) or ART (activator or replication and transcription), K8 (also termed K-bZip), and ORF45. As in vitro transmission of the virus is still laborious and inefficient, most data were obtained from PEL cells or transfection studies using permanent cell lines.

ORF50 codes for the key immediate–early regulator protein required for the switch from latent to lytic infection. ORF45 seems to be involved in counteracting the interferon response very early in infection. K8 protein is expressed with early kinetics and plays a role in HHV-8 DNA replication.

ORF50/K-RTA

ORF50 is translated from a 3.6-kb spliced mRNA that also contains the reading frames coding for K8. Due to an additional 5′ exon, the whole ORF50 protein comprises 691 amino acids with a calculated molecular weight of 73.7 kDa. It shares limited homology with the R-*trans*-activator of EBV (16 percent amino acid identity, 30 percent similarity), and was hence initially termed K-RTA. It is well established that RTA or ART of HHV-8 is the key immediate–early regulator protein of HHV-8. In cultured PEL cells, RTA is both sufficient and required for the switch from latent infection to lytic replication (Lukac et al. 1998, 1999). It *trans*-activates the expression of several early and delayed-early genes of HHV-8, including K8, ORF57 (Byun et al. 2002), and ORF59. In addition, RTA of HHV-8 interacts with CREB binding protein (CBP) and thus represses transcriptional activity of p53 and p53-induced apoptosis (Hwang et al. 2001). By direct interaction with cellular STAT3, ORF50 mediates STAT3 nuclear translocation, dimerization, and activation of STAT3-dependent transcription without prior phosphorylation of STAT3 (Byun et al. 2002).

ORF45-PROTEIN

A second immediate–early transcript of 1.7 kb was mapped to the ORF45 locus. ORF45 has the capacity to encode a protein of 407 amino acids and 43.3 kDa. Genes homologous to ORF45 of HHV-8 are conserved amongst the γ-herpesviruses. HHV-8 ORF45 seems to interact with cellular interferon-regulatory factor 7 (IRF-7) (Zhu et al. 2002). It inhibits IRF-7 phosphorylation and accumulation in the nucleus. Phosphorylation and nuclear translocation of IRF-7 normally results in activation of type I interferon genes. Thus, ORF45 could inhibit the activation of interferon very early in viral infection by blocking phosphorylation of IRF-7.

K8/K-BZIP

K-bZip is a 237 amino acid early nuclear protein. It includes a basic leucine zipper motif (K-bZIP), and is distantly related to the EBV lytic-cycle Z *trans*-activator (ZTA) protein. However, in HHV-8 the lytic cycle is induced by ORF50, and the role of HHV-8 K8 seems to be distinct. A 1.3-kb transcript that is not detectable until delayed early in the HHV-8 infectious cycle seems to contribute largely to K8/K-bZip protein synthesis (Saveliev et al. 2002). More compatible with the delayed early expression of K8 is its role as a negative regulator of ORF50 expression (Izumiya et al. 2003) and its function in DNA replication. Both in infected cells and in transfection assays, K-bZip is recruited into viral DNA replication compartments (Wu et al. 2001). Recent data indicate that K8, which also locates to the POD/ND10 domains, mediates arrest of the cell cycle in G1 phase (Wu et al. 2002). There is increasing evidence that herpesviral DNA replication takes place preferentially in G1 arrested cells to avoid competition with host-cell DNA replication (Flemington 2001). Thus, in contrast to its distant relative ZTA in EBV, the K-bZip of HHV-8

plays an important role in DNA replication and is hence also termed RAP (replication associated protein).

Virion proteins

VIRAL CAPSID PROTEINS

Detailed study of HHV-8 proteins forming the viral nucleocapsid has been hindered by the lack of an efficient lytic cell culture system. The major capsid protein is encoded by ORF25. Triplex proteins are encoded by ORF62 and ORF26, also termed minor capsid protein. The immunogenic ORF65 protein is also part of the nucleocapsid (Trus et al. 2001).

GLYCOPROTEINS

As in other herpesviruses, HHV-8 envelope glycoproteins play a crucial role in target cell recognition and entry. HHV-8 encodes at least five envelope glycoproteins, four of which (gB, gH, gL, gM) are conserved throughout the *Herpesviridae*. The function of two glycoproteins, gB and the HHV-8-specific K8.1, has been studied in more detail. Both are involved in binding of HHV-8 to its cellular attachment or entry receptors, heparan sulfate, and integrin $\alpha_3\beta_1$, respectively.

Glycoprotein K8.1

The gene encoding glycoprotein K8.1 (gpK8.1) is located approximately in the middle of the HHV-8 genome (Figure 1) within a block of conserved genes. However, as the designation as gpK8.1 indicates, it does not share recognizable homology with genes present in any other herpesvirus. gpK8.1 is translated from alternatively spliced messages giving rise to two variants, gpK8.1A and gpK8.1B, the larger A form being predominant. gpK8.1 is a major target for the humoral immunoresponse, and the glycoprotein is thus frequently a component of serological assays for HHV-8 (Chandran et al. 1998; Raab et al. 1998). gpK8.1 is part of the virion envelope and involved in attachment to target cells by binding to cell surface heparan sulfate (Birkmann et al. 2001).

Glycoprotein B

The conserved herpesvirus glycoprotein B (gB) is encoded close to the left end of the HHV-8 L-DNA (Figure 1). Like gpK8.1, gB has been shown to be part of the virion envelope. It binds to cell surface glycosaminoglycans (Akula et al. 2001). In addition, gB binds to integrin $\alpha_3\beta_1$, and this interaction seems to be involved in the entry of HHV-8 into target cells (Akula et al. 2002). The use of integrins as an entry receptor suggest that HHV-8 enters the cell by endocytotic pathways. This, however, is rather unusual for a herpesvirus. Although endocytosis of virions has been shown to occur with other herpesviruses, especially herpes simplex virus (Nicola et al. 2003), the biologically relevant way of infection by a herpesvirus is usually fusion of the virion envelope with the cytoplasma membrane at neutral pH.

Latent proteins

It is a common feature of oncogenic viruses that lytic replication is turned off in the vast majority of transformed cells. Essentially, this holds true for HHV-8. At least in Kaposi's sarcoma lesions and primary effusion lymphoma cells, expression of HHV-8 structural proteins is observed in only few cells (Figure 2a, b), whereas the viral genome is present in almost all tumor cells in a latent state with only few genes being expressed (Figure 2c, d). Although this observation does clearly not exclude that the lytic cycle genes play a role in HHV-8 pathogenesis, the few latent genes expressed by the vast majority of cells are particularly important for understanding HHV-8 biology and pathogenesis. Unfortunately, known latently expressed genes of EBV and, with few exceptions, HVS are not conserved in KSHV. Until recently, latent transcripts have been identified from only three loci of the HHV-8 genome. The major latency locus was found close to the right end of the genome (Figure 1). It comprises genes encoding the latency associated nuclear antigen 1 (LANA-1), a viral cyclin D homologue (k-cyclin, Figure 2d), and the viral anti-apoptotic flice inhibitory protein (v-Flip). Several transcripts of K12 (Kaposin) are also detectable both in KS and PEL. The third locus maps to the middle of the genome where various genes with homology to the interferon-regulatory protein family of transcription factors can be found. At least in PEL cells, two of these transcripts can be detected in latent infection.

LATENT NUCLEAR ANTIGEN 1 (LANA-1, LNA-1)

An area close to the right end of the HHV-8 L-DNA was consistently found to be transcriptionally active in latency. It comprises *orf71/vFLIP*, *orf72/k-cyclin*, and *orf73/LANA-1*. LANA-1 (LNA-1) was initially identified as the major antigen detected by KS patient sera in latently infected PEL cells (Gao et al. 1996a; Rainbow et al. 1997). It is now clear that LANA-1 is important for maintenance of the episomal HHV-8 genome in latently infected cells (Ballestas et al. 1999; Ballestas and Kaye 2001). It can therefore be seen as a functional analog of the Epstein–Barr virus nuclear antigen 1, which mediates maintenance of the latent EBV-episome by binding to the plasmid origin of replication, oriP. However, the *cis*-sequence required for HHV-8 LANA-1 to fulfill its function seems to be located within the high-density terminal repeats (Hu et al. 2002). Due to their high GC-content, the H-DNA differs clearly

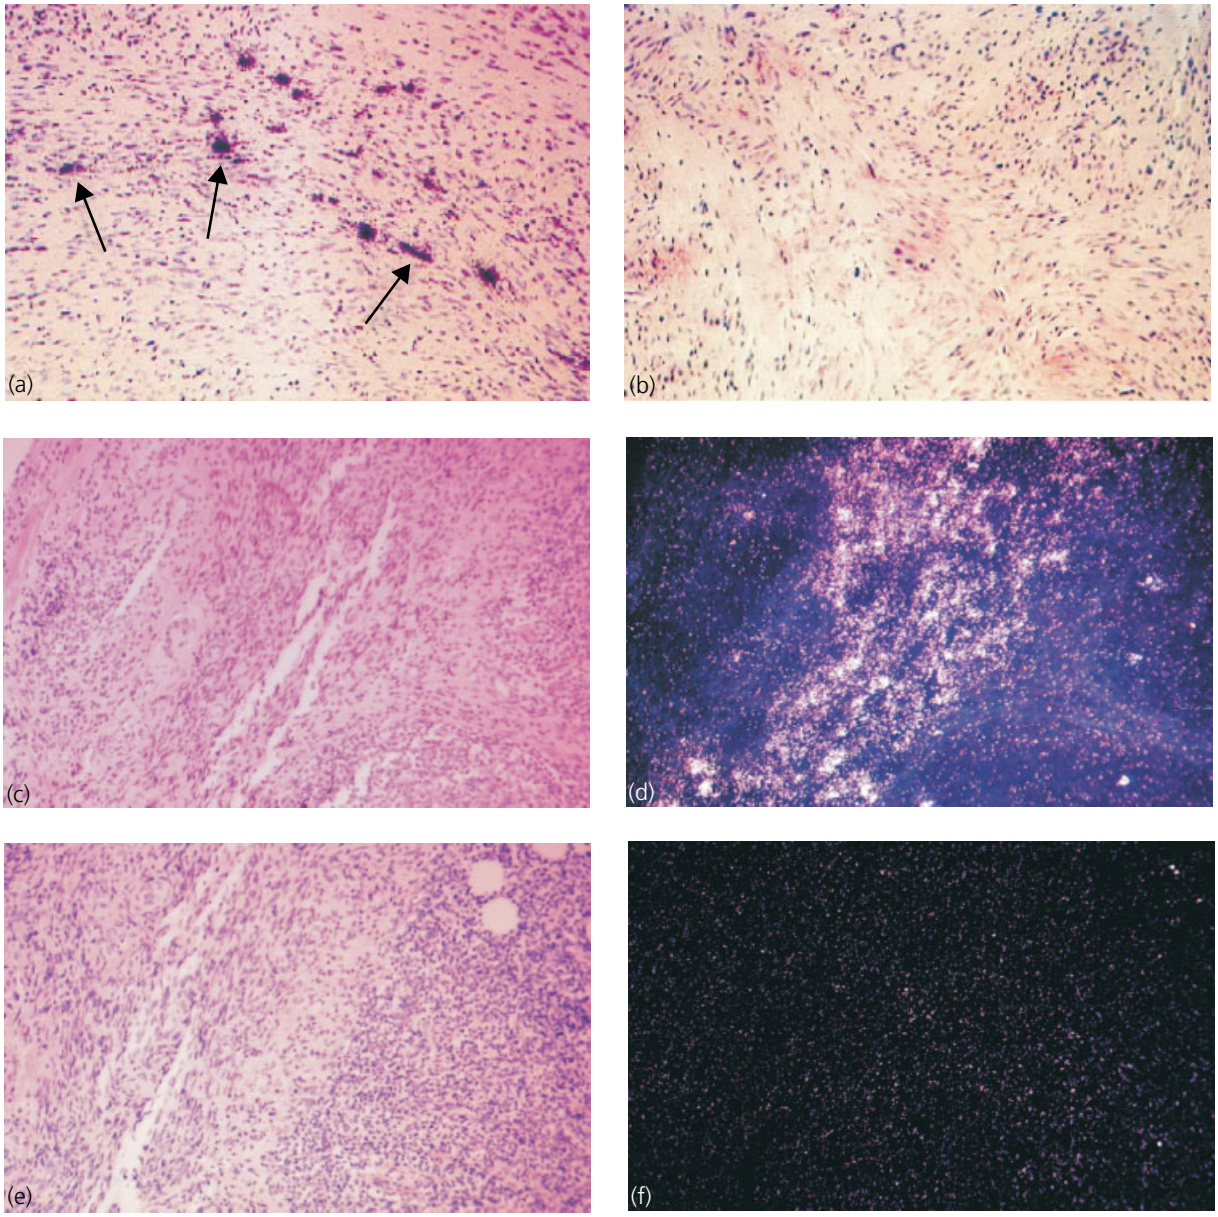

Figure 2 *Expression of HHV-8 genes in Kaposi's sarcoma. Lytic cycle genes like the minor capsid protein are detectable in only a few cells in a KS lesion* **(a)**. *The majority of spindle cells carry the HHV-8 genome in a latent state, and transcripts mapping to the k-cyclin locus are detectable* **(d)**. **(a)** *Productively HHV-8-infected cells in KS tumors were identified by in situ hybridization with strand-specific radiolabeled RNA probes directed against the mRNA coding for the HHV-8 minor capsid protein (VP23) Signals can be seen overlying single cells* **(a)**, *which are arranged in clusters between the KS spindle cells. HHV-8-positive cells are marked by arrows. Their distribution suggests that at least part of the positive cells are monocytes. Magnification, ×3 500.* **(b)** *Control hybridization. No staining was observed when a surplus of the unlabeled sense-strand RNA probe was applied to the tissue sections simultaneously with the radiolabeled antisense RNA probe. Magnification ×3 500. (c,d) Prominent signals in the majority of KS spindle cells were obtained when a probe against k-cyclin was used (c, bright field; d, dark field). A consecutive section of the same KS tissue specimen was hybridized with a HHV-8 minor capsid protein probe (VP23; e, bright field; d, dark field). The VP23 gene was not expressed in this section, indicating a more predominantly latent infection than in the sample shown in* **(a)** *(modified from Stürzl et al. (1999) and Blasig et al. (1997) with permission).*

from oriP or other eukaryotic origins of DNA replication. In addition to its well established function in maintenance of the viral genome, LANA-1 has been described to inhibit p53 and to provide protection from cell death (Friborg et al. 1999; Radkov et al. 2000). Recent data indicate that LANA stimulates S-phase entry by stabilizing β-catenin (Fujimuro et al. 2003). In summary, the latency-associated nuclear antigen 1 of HHV-8 is a multifunctional protein involved in maintenance episomal DNA, transcription regulation, and cell cycle control possibly contributing to cell transformation.

VFLIP

The viral FLIP (FLICE/caspase-8 inhibiting protein) is homologous to a cellular apoptosis inhibitor. Bi-cistronic transcripts comprising both the viral cyclin-D homologue and vFlip are detectable in latently infected cells (Figure 2b). It may play an important role in HHV-8 pathogenesis by blocking apoptosis induced by antiviral cytotoxic T cells (Thome et al. 1997) or growth factor withdrawal (Sun et al. 2003).

K-CYCLIN

Transcription of the HHV-8 encoded cyclin D homologue (k-cyclin) is driven from the same latent promoter as transcription of ORF73/LANA. It is the first gene on a bicistronic message also encoding vFLIP. k-Cyclin has been shown to associate with the catalytic subunit cdk6 to form an active holoenzyme (Li et al. 1997; Godden-Kent et al. 1997). This complex is able to phosphorylate retinoblastoma protein and to stimulate cell cycle progression from G1 to S in quiescent fibroblasts. It is especially important that the activity of the k-cyclin/cdk6 holoenzyme was resistant to inhibition by CDK inhibitory proteins $p21^{cip1}$ and $p27^{Kip1}$ (Swanton et al. 1997). These distinctive features of k-cyclin biochemistry were expanded by two papers published later (Ellis et al. 1999; Mann et al. 1999). Not only is the k-cyclin/cdk6 complex resistant to inhibition by $p27^{kip1}$, it also has a broader substrate range including $p27^{kip1}$ and substrates of cdk2. Phosphorylation of $p27^{kip1}$ results in the proteolytic degradation of this CDK-inhibitor and progression of cells arrested in G1 to S (Ellis et al. 1999; Mann et al. 1999). Deregulation of the G1/S restriction point is a feature shared by many tumor cells and DNA tumor viruses (reviewed by Pines (1995)). It is therefore intriguing to speculate that k-cyclin is involved in HHV-8 pathogenesis. However, it must be noted that at present there is no direct, experimental evidence for a transforming ability of the cyclin D homologue encoded by HHV-8, and the viral cyclin homologue has been shown to be dispensable for oncogenic transformation by the closely related herpesvirus saimiri (Ensser et al. 2001).

K12

A HHV-8 transcript of 0.7 kb (T0.7) was originally described as being abundantly expressed in nonstimulated PEL cells. T0.7 mRNA, which contains the putative open reading frame K12, is also detectable in the majority of KS spindle cells. The oncogenic potential of K12 in rodent fibroblast transformation assays was not very pronounced (Muralidhar et al. 1998) and the data remain controversial. It is therefore not yet possible to assess the oncogenic potential of K12 or T0.7 with certainty.

VIRAL INTERFERON REGULATORY FACTORS

The HHV-8 genome contains four genes with homology to cellular interferon regulatory factors (vIRFs), termed K9, K10, K10.5, and K11. At least one of these transcription factors, K10.5, is expressed in latently infected PEL cells. Whereas the vIRF-1 encoded by K9 has been shown to antagonize the action of class I interferons, the function of the latently expressed K10.5 is less clear as yet. It is interesting, however, to note that its closest cellular homologues are IRF-4 and the interferon consensus sequence binding protein, ICSBP. Expression of both IRFs is restricted to lymphoid cells. IRF-4 is clearly important for differentiation and proliferation of B-lymphocytes (Pernis 2002).

Inflammatory cytokines and related genes encoded by HHV-8

HHV-8 codes for several proteins which are not generally conserved amongst the different herpesvirus families, but which share striking homology with genes of the host cell. It is very likely that these genes have been captured from the host cell during evolution (Table 2). Interestingly, whereas the cellular genes usually consist of several exons, their viral homologous are usually translated from nonspliced messenger RNA. It is thus likely that these genes have been acquired from cellular mRNAs after reverse transcription. With the few exceptions discussed above (k-cyclin, vFlip, K10.5), these virus-cell homologous genes are not expressed in latently infected cells, but seem to be active early in the lytic replication cycle. Typically, they are coding for proteins interfering with the immune system, for enzymes of the nucleotide metabolism, and for putative regulators of cell growth. Thus, their main function seems to be to provide an environment suitable for replication of the virus by counteracting early immune responses (IRFs, anti-apoptotic proteins like vbcl-2, complement regulatory protein homologue CCPH), providing sufficient pools of nucleotides for viral replication or to increase the number of target cells for HHV-8 infection (macrophage inflammatory protein homologues, viral interleukin-8 receptor, interleukin-6). It seems to be a 'rule of thumb,' that such viral genes encode proteins which are usual functional agonists of their cellular counterparts. However, they frequently escape from the usual regulatory mechanisms. Examples are receptors with constitutive activity (e.g. the viral interleukin-8 receptor), a viral cyclinD homologue that escapes from control by cyclin inhibitory proteins, or cytokines like the viral interleukin-6 that are able to bind to a cellular receptor without additional molecules. It is possible that HHV-8 encoded cytokines or cytokine receptors are involved in KS or PEL pathogenesis by paraendocrine mechanisms. Although the HHV-8 genome is present in a latent state in the vast majority of tumor cells, a few cells in a lesion express HHV-8 lytic cycle genes.

VIRAL INTERLEUKIN-6

The open reading frame K2 of HHV-8 encodes viral IL-6 (vIL-6), a protein with moderate yet significant

Table 2 *HHV-8 genes putatively involved in pathogenesis*

ORF	Gene product	Suggested function in pathogenesis	Experimental evidence
K1	Nonconserved transmembrane glycoprotein	Positional and (possibly) functional analogue to other rhadinoviral oncoproteins	Transformation of Rat1 cells; recombinant herpesvirus saimiri: lymphocyte immortalization, lymphoma induction (Lee et al. 1998)
K2	Viral IL-6	Paracrine growth stimulation independent of gp80	Proliferation of B cells; IL-6Rα chain not required (Chatterjee et al. 2002; Burger et al. 1998; Molden et al. 1997)
vMIPs (K4, K4.1, K5)	Viral macrophage inflammatory proteins	Angiogenesis; attraction of Th2 lymphocytes	Binding to both CC and CXC receptors; attraction of eosinophils; induction of angiogenesis (Boshoff et al. 1997)
K9, K10, K10.5, K11	Interferon response factor homologues	Interfering with the antiproliferative action of IRF-1	K9: antagonistic to IRF-1, transformation of 3T3 cells (Li et al. 1998)
K12	Kaposin A	Transformation	Transformation of Rat-3 cells; increased cellular adhesion
ORF16	vbcl-2	Stabilizing productively infected cells	Anti-apoptotic activity
ORF71	vFLIP	Stabilizing latently infected cells	In situ: increased expression correlates with reduced apoptosis
ORF72	k-Cyclin	Dysregulated cell cycle progression, inhibits cell cycle arrest by p53	Activates cdk6, evades inhibition by CDK-inhibitors, destabilizes p27 (Swanton et al. 1997)
ORF73	LANA-1	Maintains latent viral infection	Mediates HHV-8 DNA persistence (Ballestas et al. 1999)
ORF74	vIL-8R	Angiogenesis, transformation of endothelial cells	Constitutively active; induces VEGF secretion, transforms rodent fibroblasts; KS-like lesions in transgenic mice (Bais et al. 1998; Yang et al. 2000)
K15	Integral membrane protein reminiscent of EBV LMP-2	Differentiation and proliferation of B lymphocytes	

EBV, Epstein–Barr virus; IL-6, interleukin-6; IL-6Rα, interleukin-6 receptor α-chain (gp80); IRF, interferon regulatory factor; k-cylin, KSHV-encoded cyclin D homologue; LANA-1, latent nuclear antigen-1; LMP-2, latent membrane protein-2 of Epstein–Barr virus; ORF, open reading frame; VEGF, vascular endothelial cell growth factor; vFLIP, viral FLICE inhibitory protein; vIL-8R, viral interleukin-8 receptor homologue.

homology to the multifunctional human cytokine IL-6 (hIL-6) (Neipel et al. 1997a). The vIL-6 cytokine is functional and supports the proliferation of both murine and human IL-6-dependent cells (Burger et al. 1998). Both human and viral IL-6 are produced in KS lesions and the proliferation of cultured spindle cells can be stimulated with oncostatin M and hIL-6 (Masood et al. 1994; Miles et al. 1992). Nevertheless, the relevance of IL-6 for KS pathogenesis has been questioned as some groups were not able to detect expression of the IL-6 receptor α-chain (IL-6Rα) by KS spindle cells (Murakami Mori et al. 1995). The IL-6R consists of two chains. The β-chain, also termed gp130, is almost ubiquitously expressed. It is responsible for ligand-dependent signal transduction and is shared by several receptors of four-helical cytokines such as IL-6, IL-11, ciliary neurotrophic factor, cardiotrophin-1, oncostatin M, and leukemia inhibitory factor. The β-chain alone is not sufficient for hIL-6 binding. hIL-6 first needs to bind to the second chain (IL-6Rα), and this complex then associates with gp130. There is compelling evidence that IL-6Rα is not required for binding of vIL-6 to the signal transducer gp130 (Chow et al. 2001; Li et al. 2001; Molden et al. 1997). Thus, vIL-6 can induce gp130 signal transduction on almost any cell. This may be important for autocrine growth stimulation of HHV-8 infected cells, as expression of the gp80 chain is reduced by interferon-α. By producing vIL-6 which is not dependent on gp80, HHV-8 infected cells escape from one of the mechanisms of growth control by interferon-α (Chatterjee et al. 2002).

CHEMOKINES ENCODED BY HHV-8

Three genes with homology to the family of CC chemokines are located in the same nonconserved region of the HHV-8 genome as vIL-6 (Figure 1, Table 2).
The proteins encoded by the open reading frames K4 and K6 are homologous to the macrophage inflammatory protein 1α (MIP-1α). They have been termed vMIP-II and vMIP-I, respectively (Nicholas et al. 1997; Russo et al. 1996). The amino acid sequence identity of these viral proteins to their cellular counterpart is only about 30 percent, but 48 percent of the viral sequences are identical to each other. This could indicate a gene duplication event that occurred in the evolution of the genes rather than independent acquisition from the host cell genome. Another HHV-8 reading frame, K4.1, is also homologous to the CC chemokine family, with similarity to both MIP-1β and macrophage chemoattractant protein. Functional data are available for vMIP-I (K6) and vMIP-II (K4). vMIP-II binds efficiently to the CC-chemokine receptor CCR3 (Boshoff et al. 1997). In contrast to cellular MIP-1α, it does also bind to CXC-chemokine receptors such as CXCR4, albeit with lower affinity. The CC-chemokine receptor CCR3 is known to be relevant for the chemoattraction of both eosinophil granulocytes and Th2 lymphocytes. Correspondingly, a potent chemoattractive effect of vMIP-II on eosinophils was described (Boshoff et al. 1997). In contrast to cellular MIP-1α and to the CC-chemokine RANTES, both vMIP-I and vMIP-II were highly angiogenic in the chorioallantoic assay (Boshoff et al. 1997). The chemokine homologues encoded by HHV-8 could thus contribute to two features of KS histology: the presence of inflammatory infiltrates containing Th2 lymphocytes, and the prominent angiohyperplasy.

VGPCR/VIL-8R

Similarly to most other rhadinoviruses, HHV-8 encodes a protein with homology to the family of G-protein coupled receptors (GPCR) with seven transmembrane regions (Table 2). The HHV-8 gene is most homologous to the human IL-8R and hence termed vIL-8R. This viral receptor is capable of activating the protein kinase C pathway, regardless of whether a suitable chemokine is present or not. This constitutive activity was sufficient to enhance the proliferation of transfected primary rat fibroblasts (Arvanitakis et al. 1997). Moreover, the transfection of vIL-8R induced focus formation in fibroblasts with an efficiency comparable to the m1 muscarinic receptor, but independently of an extracellular ligand. vIL-8R transformed cells efficiently formed tumors in nude mice (Bais et al. 1998). Transgenic mice were generated that expressed vIL-8R under control of the CD2 promoter on lymphoid cells. Interestingly, this resulted in angioproliferative lesions in multiple organs. Histologically, these lesions strikingly resembled KS (Yang et al. 2000). Thus, the constitutively signaling viral IL-8R homologue is another potential HHV-8-encoded oncogene.

CLINICAL AND PATHOLOGICAL ASPECTS

INTRODUCTION

Extensive studies on HHV-8 molecular epidemiology have shown that, although not discovered until 1994, HHV-8 has most likely been present in the human population for at least 35 000–60 000 years (Hayward 1999). Thus, HHV-8 is a typical herpesvirus which has evolved to stay precisely balanced with its host organism. As a consequence, HHV-8 infection is usually benign and often asymptomatic. Nevertheless, persistent HHV-8 infection is clearly associated with three diseases: Kaposi's sarcoma, multifocal Castleman's disease, and primary effusion lymphoma, which represent a spectrum from a hyperproliferative process (Kaposi's sarcoma) to true monoclonal lymphoma (primary effusion lymphoma). All three diseases occur more frequently in immunosuppressed patients, especially in HIV-infected patients.

EPIDEMIOLOGY

HHV-8 DNA is almost invariably detectable in all epidemiological forms of Kaposi's sarcoma, in primary effusion lymphomas, and most cases of multifocal Castleman's disease. In contrast, attempts to amplify HHV-8 DNA from various other malignant and non-malignant diseases, as well as healthy individuals were either unsuccessful or difficult to reproduce. Thus, it appears that at least amongst populations of the northern hemisphere, the detection of HHV-8 DNA is restricted to KS, PEL, and MCD, where it is regularly found. Most human tumor viruses are relatively widespread when compared to the frequency of the malignancy they cause. This is true for Epstein–Barr virus, the human herpesvirus most closely related to HHV-8, and for human papillomaviruses. The epidemiology of AIDS-associated KS in the metropolitan areas of the northern hemisphere suggested that a relatively infrequent, sexually transmitted agent is involved in KS pathogenesis (Figure 3). This poses three important epidemiological questions: firstly, is the HHV-8 prevalence significantly increased in KS risk groups, as compared to the general population? Second, does the infection precede KS development? Third, are the modes of transmission compatible with the claimed transmissible agent? Nucleic acid detection is not sufficient to answer these questions, as the high level of viral replication found in immunosuppressed patients makes detection of viral genomes much more likely in this group. Serological studies are more suitable. The first serological studies were solely based on immunofluorescence techniques using HHV-8-positive cell lines derived from primary effusion lymphomas (Cesarman et al. 1995b). In the meantime, enzyme linked immunosorbent assays utilizing purified virus, recombinant antigen, or synthetic peptides are also available. The validity of these assays, especially when it comes to the crucial question of seroprevalence in persons not at risk for KS, is still under debate (Pellett et al. 2003). This is essentially due to the high interassay variability observed with low-titered sera from non-KS patients. However, as justified as it may be, this debate should not obscure three important findings: firstly, the prevalence of (high) anti-KS antibody titers correlates very well with KS. This is true both when various AIDS-transmission groups are compared within one geographic area, and when areas of low KS prevalence (e.g. Northern Europe or the United States) are compared with regions where KS is endemic, e.g. Mediterranean Europe or parts of Africa (Gao et al. 1996b; Kedes et al. 1996; Miller et al. 1996; Simpson et al. 1996). HHV-8 seroprevalence is in the range from 0 to 5 percent in the general population of northern Europe and the United States. The increased incidence of Kaposi sarcoma in Italy is reflected by a higher HHV-8 seroprevalence, especially in southern parts of Italy, including Sicily and Sardinia. Depending on the geographic area, HHV-8 seroprevalence in Italy can be as high as 45 percent (Santarelli et al. 2001), with an average of about 12 percent in Mediterranean countries. In sub-Saharan Africa, however, where KS has been described as the most frequent malignancy even before the beginning of the AIDS epidemic, HHV-8 seroprevalence is usually above 60 percent. Second, HHV-8 seroconversion or at least a marked increase in anti-HHV-8 antibody titer precedes KS development in homosexual AIDS patients (Gao et al. 1996a; Martin et al. 1998). Third, high anti-HHV-8 antibody titers were also associated with the number of homosexual partners and a history of other sexually transmitted diseases (Martin et al. 1998). In summary, serological data largely agree that the titer of anti-HHV-8 antibodies reflects KS or the risk of KS development. Although some uncertainty still remains with the current serological assays and reactivation of HHV-8 cannot be excluded as the reason for the markedly increased anti-HHV-8 titers in KS patients, the high levels of antibodies in groups at risk of KS and seroconversion preceding the onset of the disease clearly hint at a pathogenetic role of HHV-8 infection in KS.

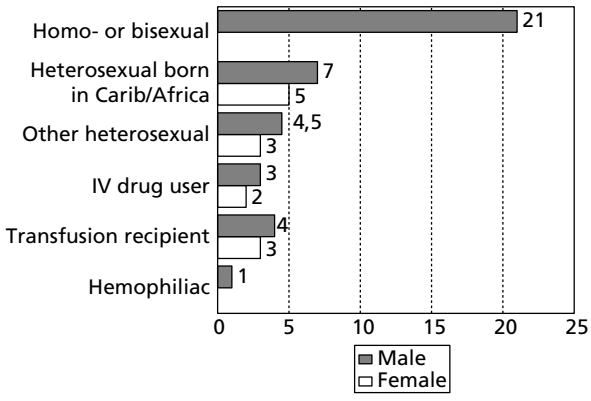

Figure 3 *Percentage of AIDS patients with Kaposi's sarcoma by HIV transmission group. The data are taken from Beral et al. (1990). A total of 90 990 persons with AIDS were included in the study. Whereas 21 percent of the HIV-infected patients in the homo- or bisexual transmission group developed KS, only 1 to 4 percent of patients infected via blood or blood products suffered from this tumor.*

CLINICAL MANIFESTATIONS

Primary infection

Like other herpesviruses, HHV-8 is usually entirely benign under normal conditions. Nonsexual transmission is most likely predominant in areas of high HHV-8 prevalence, e.g. southern European and African countries, and the virus has been detected in the saliva of children seropositive for HHV-8, making it likely that transmission via saliva is a main route in this age group.

However, modes and routes of transmission in areas of low HHV-8 prevalence are less clear. The epidemiology of AIDS-associated KS in these areas suggests transmission in the context of sexual activity. Among men, HHV-8 seroprevalence correlates with the number of homosexual partners and is a risk factor for KS development (Martin et al. 1998). Primary infection is usually asymptomatic but may be associated with a febrile illness and maculopapular rash in children (Andreoni et al. 2002). After primary infection, life-long latency is likely established in memory B cells which becomes only manifest as a disease if the virus–host balance is severely disturbed, e.g. by immunosuppression. In the latter case, three malignant diseases are clearly associated with HHV-8 infection: Kaposi's sarcoma, primary effusion lymphoma, and multifocal Castleman disease.

Kaposi's sarcoma

EPIDEMIOLOGY

Kaposi's sarcoma occurs in four epidemiological variants. The classical form afflicts mainly elderly men of southeastern European descent. It was described in 1872 by Moriz Kaposi as 'sarcoma idiopathicum multiplex hemorrhagicum.' The incidence of classic KS in northern Europe is less then 1/100 000 total population, and about ten-fold higher in endemic regions of southern Europe. The male/female ratio of classical KS is about 10/1. African endemic KS had already been described before the advent of the human immunodeficiency virus. The prevalence of African endemic KS is as high as 12 percent in certain areas of sub-Saharan Africa (Wabinga et al. 2000). Iatrogenic KS occurs in therapeutically immunosuppressed patients. The incidence of post-transplant KS correlates with the general HHV-8 seroprevalence. It is thus more frequent in southern Europe and the Arabian peninsula, where as much as 5 percent of kidney transplant recipients may develop KS (Lesnoni La Parola et al. 1997; Qunibi et al. 1988). The unusual distribution of AIDS-associated KS, the fourth epidemiological form, triggered the search for an infectious agent other than HIV in KS (Beral et al. 1990). At the beginning of the AIDS epidemic, up to 30 percent of male homosexual HIV patients developed this unusually aggressive form of KS, in contrast to only 1 percent of age- and sex-matched HIV-infected patients with hemophilia.

SYMPTOMS AND SIGNS

Initially, KS lesions present as pink or red macular eruptions that progress to plaques and nodules, which subsequently frequently ulcerate. The lesions are often accompanied by lymphedema, which, especially at the nodular and ulcerating stage, cause discomfort and pain. From the very beginning, the clinical presentation of all forms of KS is characterized by a multifocal, often symmetric distribution of the lesions. The most important predilection site is the skin, especially the skin of the lower limbs. However, lymph nodes and viscera are involved in at least 50 percent of cases, even in the more benign classic KS. The disease may afflict any organ with the apparent exception of the central nervous system. The progression from patch to plaque and nodule may take several years in classic KS, and single lesions may even disappear spontaneously. Classic KS is a chronic disease that progresses slowly over many years. Mean survival time of classic KS is 10–15 years and many patients die of an unrelated cause. Other forms of KS, however, are much more aggressive and may progress quickly, often within a few month. This holds particularly true for AIDS-associated KS (Figure 4). A standardized staging system for KS has been developed by the AIDS Clinical Trial Group (Krown et al. 1997). African endemic KS occurs in at least three different clinical pictures: a more slowly progressing form in young adults that resembles European classic KS, an aggressive cutaneous form with frequent visceral involvement that is fatal within 5–7 years, and a very aggressive lymphadenopathic form that occurs in young children (mean age, 3 years; male/female ratio, 3/1).

PATHOLOGY

Although Kaposi's sarcoma occurs in four distinct epidemiological forms which also differ in clinical course and prognosis, all forms share the same histopathology (Figure 2) and can be considered one disease entity.

At least in its early stages, KS is not a typical sarcoma. It develops in a polyclonal fashion. Multiple lesions appear simultaneously, often with an almost symmetrical distribution which is not compatible with metastatic tumor growth. In contrast to other sarcomas, classic KS may wax and wane over decades, and single lesions may disappear completely. This was also observed for the more aggressive AIDS-associated form of KS, where complete remissions were seen during antiretroviral combination therapy (Lebbe et al. 1998). Although molecular data on the clonality of several KS lesions in a single patient are conflicting, it appears that, at least in its early stages, KS is not a monoclonal tumor (Delabesse et al. 1997; Gill et al. 1997). However, late nodular lesions may eventually progress to true sarcoma as indicated by clonality (Gill et al. 1998; Rabkin et al. 1997). The histological picture of (early) KS lesions is not typical for other sarcomas. The lesions contain many different cell types. The so-called KS spindle cells are considered the tumor-defining, malignant cell type of the disease. KS spindle cells are thought to be derived from lymphatic endothelial cells (Weninger et al. 1999). However, they are not the dominant cell type until late stage disease. KS lesions begin as subtle neovascularization (Ruszczak et al. 1987a), and the pathognomonic spindle cells are not yet detectable. In addition, KS

Figure 4 *AIDS-associated Kaposi's sarcoma. One of the first AIDS patients seen in New York in 1981. Initially, the 36-year-old man presented with only a few macular KS lesions on his face and oral mucosa, and there were no lesions seen on his back* **(a)**. *A follow-up photograph of the same patient was taken 6 months later* **(b)**. *It illustrates the rapid development of disseminated Kaposi's sarcoma plaques in immunosuppressed patients (from Friedman-Kien,* Color atlas of AIDS, *with permission).*

lesions contain infiltrating inflammatory cells and multicentrically arising vascular endothelia forming capillaries and other vessels (Ruszczak et al. 1987b). The proliferation of cultured spindle cells is highly dependent on inflammatory cytokines and, with a few exceptions, KS spindle cells are not tumorigenic in nude mice (Nakamura et al. 1988; Salahuddin et al. 1988).

THERAPY

Treatment of Kaposi's sarcoma depends not only on the extent of the tumor and organ involvement, but especially on the type of KS (Hengge et al. 2002). A staging system has been provided by the AIDS Clinical Trials Group (Krown et al. 1997). Classic KS is initially treated with local therapy (excision of single lesions, radiation, intralesional and topical chemotherapy using vinblastine or vincristine). However, the lesions usually reappear. Systemic chemotherapy is used when classic KS is more advanced, disseminated, and symptomatic. The more aggressive forms of African KS (except lymphadenopathic KS in children) also respond well to systemic chemotherapy. Cytotoxic agents used in KS chemotherapy include liposomal doxorubicin, bleomycin, vinca alcaloids, and paclitaxel. Since it is known that HHV-8 is most likely required albeit not sufficient to cause KS, specific antiviral treatment has also been used in KS therapy. HHV-8 replication can be inhibited with foscarnet and ganciclovir in cell culture systems. In one study, a 75 percent reduction in the rate of new KS was seen after high-dose ganciclovir treatment for cytomegalovirus retinitis (Martin et al. 1999). However, data on the treatment of pre-existing KS lesions with ganciclovir or foscarnet are less consistent. The use of interferon-α seems to be more promising. A reduction in up to 30 percent of individuals has been reported following the therapy with high doses of interferon-α (Krown 2001). The therapeutic efficacy of interferon-α is not only due to its antiviral activity. Class I interferons have also been shown to reduce cell proliferation and angiogenesis. Iatrogenic KS usually regresses after reduction of immunosuppressive therapy. However, when immunsuppressive therapy is reinitiated, KS lesions often reappear. Thus, chemotherapy is often used in more disseminated disease. Local or systemic therapy does not increase the survival time of patients with AIDS-KS. The most effective treatment for AIDS-KS is highly active antiretroviral therapy (HAART) (Cattelan et al. 2002). Reconstitution of the immune system by HAART frequently results in complete remission of AIDS-KS.

PRIMARY EFFUSION LYMPHOMA

Primary effusion lymphoma is a rare non-Hodgkin B-cell lymphoma which is primarily seen in immunosuppressed patients. In contrast to KS, which has features of both a hyperproliferative inflammatory lesion and malignant neoplasia, PEL represents a more typical, monoclonal neoplastic process. The name primary effusion lymphoma or body-cavity-based lymphoma (BCBL) indicates that the disease manifests by pleural, pericardial, or peritoneal effusion, often without a solid tumor. Primary effusion lymphomas regularly contain HHV-8, and 50 percent of the cases are also positive for Epstein–Barr virus. Whereas HHV-8 is invariably

present in PEL, it has not been found in any other lymphoma (Cesarman et al. 1995a). PEL cells do not express B- or T-cell antigens. It is indicated by immunoglobulin rearrangement, lack of Bcl-6 expression, and expression of syndecan-1 that PEL cells are derived from post-germinal B cells. AIDS-associated PEL is usually highly aggressive with a mean survival from diagnosis of 5 to 7 months. Several permanent cell lines have been established from PEL cases. The HHV-8 genome is maintained in cultured PEL cells in a latent state with only a few genes being expressed. However, lytic replication can be induced in cultured PEL cells by chemicals such as tetra-phorbol acetate or sodium butyrate. Thus, cell lines derived from PEL are at present an invaluable tool in KS research.

MULTIFOCAL CASTLEMAN'S DISEASE

Multifocal or multicentric Castleman's disease is an atypical lymphoproliferative disorder. The plasma cell type, but not the hyaline vascular type, of MCD is associated with HHV-8 infection and epidemiologically related with both AIDS-associated and classic KS. However, in contrast to both KS and PEL, even the plasma cell type of MCD is not invariably positive for HHV-8. This may indicate that MCD represents a diverse group of lesions. Clinically, MCD is characterized by generalized lymphadenopathy, hypergammaglobulinemia, and fever. Histological examination of affected lymph nodes reveals large follicles, expanded germinal centers separated by vascular lymphoid tissue. HHV-8 harboring cells in MCD resemble immunoblasts which reside in the mantle zone of B-cell follicles. These isolated immunoblasts may eventually form monoclonal, microscopic lymphomas (Dupin et al. 2000), and monoclonal plasmablastic lymphoma may develop in MCD patients. The plasmablastic, HHV-8 associated variant of MCD is frequently resistant to systemic chemotherapy and lethal. Systemic symptoms of MCD have ben shown to correlate with increased serum levels of interleukin-6. Treatment with both anti-IL-6 antibodies, as well as an antibody directed against the interleukin-6 receptor efficiently reduces fever, fatigue, and lymphadenopathy. Whereas HAART has clearly reduced the incidence of KS and PEL, an increase in fatal MCD has been observed following highly active antiretroviral therapy (Zietz et al. 1999).

MODELS OF PATHOGENESIS

Consistent detection of viral DNA in tumor tissue is not sufficient to prove that a virus is involved in oncogenesis. In theory, different roles are possible for HHV-8 in KS pathogenesis (Neipel et al. 1997c), ranging from a mere 'passenger model,' where HHV-8 would be an innocent bystander, to the role of a directly transforming virus. Several lines of evidence strongly suggest that HHV-8 plays an essential role in KS pathogenesis: the virus is invariably present in KS, HHV-8 infection precedes KS development, the virus is present in the tumor cells themselves, and it is rather infrequently found outside the population at risk of KS. Moreover, HHV-8 belongs to a group of herpesviruses known to be oncogenic. It is difficult, however, to assess the pathogenic potential of HHV-8 more reliably without identification of the genes and mechanism involved in pathogenesis. Research on HHV-8 pathogenesis is hampered by the lack of a cell culture system for transformation as it exists for EBV or herpesvirus saimiri. In addition, several attempts have been made to establish animal models for HHV-8 proliferative diseases. Unfortunately, infections of various primates did not result in overt disease. Studies using rodents transgenic for single HHV-8 genes were more successful. However, results from such experiments must be interpreted with great caution, no matter how tempting the resemblance of lesions in mice transgenic for vIL8R to KS may be (Yang et al. 2000). In summary, several genes with oncogenic potential have been identified in cell culture transformation assays or transgenic animals, and various models were developed. However, statements on their relevance in KS, PEL, and MCD remain speculative to date.

At least two concurring models exist for the role of HHV-8 in KS pathogenesis. The 'cytokine model' emphasizes the role of inflammatory cytokines induced or produced by HHV-8. A closer look at the clinical course and histopathology of KS raises doubts about the relevance of 'classical,' transforming genes for the pathogenesis of this peculiar tumor. The peculiar pathology of KS hints at a more complex, indirect mechanism of pathogenesis. Based on clinical observations and data derived from cell culture systems, models of KS pathogenesis were developed before HHV-8 was discovered. Several groups agreed upon the notion that KS develops as an interplay of inflammatory cytokines and angiogenic factors (Ensoli and Stürzl 1998; Samaniego et al. 1998), although the cytokines focused on various different reports. Amongst them are basic fibroblast growth factor, vascular endothelial growth factor (VEGF), IL-6, tumor necrosis factor (TNF)α and β, and oncostatin M. Interestingly, HHV-8 encodes or induces several cytokines with intriguing similarity to the cellular factors shown to be required for in vitro models of KS. An example is VEGF, which is secreted by cells expressing the constitutively active vIL-8R. This leads to a model of KS pathogenesis, where increased secretion of both viral and cellular cytokines, the latter in part induced by HHV-8, promote inflammatory infiltrates (vMIP, vIL-6), angiogenesis (vMIP, vIL-8R), and enhance spindle cell proliferation (vIL-6, vIL-8R via VEGF). The reliable presence of HHV-8 in the spindle cells points to additional factors beyond those induced through the 1–3 percent productively infected cells, voting for a role more compatible with a typical 'onco-

genic transformation' model by latently expressed viral genes.

Starting from the close relationship to EBV and herpesvirus saimiri, it is intriguing to assume that transmembrane proteins mimicking constitutively active receptors mechanisms – similar to those identified in EBV and herpesvirus saimiri – might be relevant for HHV-8 pathogenesis. At first sight, HHV-8 genes K1 and K15 might fall into this category. However, attempts to detect expression of these genes in latently infected tumor cells remained unsuccessful, voting against a role of K1 and K15 in transformation. Only few viral genes were found expressed in latently infected cells. These include the viral interferon regulatory factor K10.5, LANA-1, the viral cyclin D homologue, and possibly vFLIP. Although clearly not considered a common rhadinoviral oncogene (Ensser et al. 2001), the viral k-cyclin may be such a factor in KS. It is transcribed in the majority of latently infected tumor cells, and deregulation of the G1/S checkpoint is a feature common to various malignancies and human tumor viruses. k-Cyclin has been shown to overcome arrest in G1 and to force progression of the cell cycle. One physiological function of the restriction point in G1/S is to block cell division in the case of DNA damage. This is usually achieved through the activation of p53 which in turn results in an increased synthesis of cdk inhibitors such as p21. However, the k-cyclin/cdk6 complex is resistant to inhibition by several cdk inhibitors (Swanton et al. 1997). Thus, k-cyclin may not only be responsible for increased proliferation of HHV-8-infected endothelial and spindle cells, but sustained expression of k-cyclin may also result in the unrestricted acquisition of somatic mutations, eventually resulting in the malignant phenotype and monoclonality associated with advanced stage disease. As described above, LANA-1 seems to be a multifunctional protein. It is not only required for maintenance of the viral episome, but also in transcription regulation and cell cycle control possibly contributing to cell transformation. The role of K10.5 remains speculative. Its similarity to the cellular genes IRF-4 and interferon consensus sequence binding protein suggests that it may play a role in lymphocyte development.

Thus, KS may result from a complex interplay of both viral and cellular cytokines and angiogenic factors, induced by a sustained inflammatory reaction initiated by up to 3 percent productively infected cells. The viral cyclin and perhaps other latency-associated proteins, such as LANA-1, might further enhance the proliferation of KS cells and favor the development of truly malignant cells by indirect means, e.g. the reduced control of accidental DNA damage. As KS is an unusual malignancy, resembling hyperplastic, angioproliferative inflammatory changes rather than true sarcoma, such a multistep/multifactorial model might be more compatible with KS pathogenesis than classical transformation models by viral oncogenes (Stürzl et al. 2001), as described for EBV, herpesvirus saimiri, and possibly for HHV-8-associated B-cell malignancies (PEL).

PROPERTIES OF THE VIRUS

INTRODUCTION

The Epstein–Barr virus (EBV) was discovered in 1964 (Epstein et al. 1964) in the course of a sustained search (Epstein 1999) for a possible causative virus in tumor samples from cases of endemic (African) Burkitt's lymphoma (BL). EBV is a very ancient parasite of humans. The fact that EBV-like herpesviruses have been known for many years in Old World apes and monkeys (Deinhardt and Deinhardt 1979) and have now recently been found in New World monkeys (Cho et al. 2001, Wang et al. 2001) indicates that such viruses were already infecting early primates some time before the Old World/New World evolutionary split took place, about 35 Myr ago based on palaeontology (McGeogh and Cook 1994) or 45 Myr ago based on more recent DNA sequence data (Kumar and Hedges 1998). EBV infects almost all of the world's adult population and, like all human herpesviruses, establishes lifelong persistence. However, despite the trivial nature of the infection in most individuals, the virus is the most potent immortalizing agent for mammalian B cells in vitro, is associated with a spectrum of human malignant proliferations in vivo, and causes rapidly fatal malignant tumors on experimental injection in cottontop tamarins.

EBV has a restricted host range, with humans as its natural host, but certain nonhuman primates can be infected experimentally. The virus is B lymphotropic in vivo and readily infects B lymphocytes in vitro (Pattengale et al. 1973), resulting in B-cell immortalization and the generation of continuously proliferating lymphoblastoid cell lines (LCL) (Pope et al. 1968). EBV also infects squamous epithelial cells in certain pathological conditions in vivo (see later under Nasopharyngeal carcinoma and Oral hairy leukoplakia), and such cells can support full virus replication. However, in vitro infection of primary epithelial cells is problematic, and thus no fully permissive system is available for the study of individual replicative gene functions, in contrast to latent infection, which has been extensively investigated because of the ease with which immortalization of B cells can be brought about.

CLASSIFICATION

EBV is a member of the *Herpesviridae* and is in the *Gammaherpesvirinae* subfamily, genus *Lymphocryptovirus*. This classification is based on DNA homology between the EBV genome and that of other gammaherpesviruses, the G+C content of the genome and the lymphotropism of the virus.

MORPHOLOGY AND PARTICLE STRUCTURE

Like other herpesviruses, EBV has a protein core containing DNA, a nucleocapsid composed of 162 capsomers that forms an icosahedral protein shell, and

an outer envelope derived from cellular membranes and containing virus-coded glycoprotein spikes.

MOLECULAR BIOLOGY

Genome structure and function

The EBV genome is a linear molecule of double-stranded DNA that contains 184 kb (www.med.ic.ac.uk/ludwig/EBV.htm) and has coding potential for about 70 proteins. EBV DNA contains several internal repeats interspersed with unique sequences and flanked by two terminal repeat sequences (Figure 1). EBV was the first herpesvirus to be cloned (Dambaugh et al. 1980) and sequenced (Baer et al. 1984). The nomenclature for the promoters and open reading frames within the viral genome has been assigned using the abbreviated name of the *Bam*HI restriction fragment: for example, BARF1 is the first, rightward open reading frame in the *Bam*HI A fragment of the EBV genome.

Two types of EBV exist, 1 and 2 (also called A and B) (Dambaugh et al. 1986), with an overall DNA sequence homology of 70–85 percent (Sample et al. 1990). They differ in the regions of the viral genome coding for the Epstein–Barr virus nuclear antigens (EBNA) 2, 3A, B, C (Rowe et al. 1989) and the Epstein–Barr virus-encoded small RNAs (EBER) (Arrand et al. 1989). These differences are reflected in biological diversity, type 1 viruses being more efficient than type 2 at immortalization of B lymphocytes in vitro (Rickinson et al. 1987). Type 1 EBV predominates worldwide. Type 2 is rare in western societies but more common in African communities. Dual infection may occur in individuals with immunosuppression (Zimber et al. 1986; Sculley et al. 1990). However, no type-specific disease associations have been noted. In addition to EBV type variation, individual viral isolates differ in the number of tandem repeats in their internal DNA repeat sequences. This heterogeneity can be used to define individual EBV isolates (Falk et al. 1995).

Latent infection of a B lymphocyte is associated with circularization of the EBV genome to form an episome (Lindahl et al. 1976), which later amplifies to give multiple copies. Genome circularization is achieved by covalent linkage of the terminal repeat elements, and the number of repeat sequences varies with different circularization events. Thus, when the viral episome is passed from one latently infected cell to a daughter cell (without linearizing) the number remains the same, indicating viral clonality. Estimation of the terminal repeats can therefore be used to determine whether virus infection of cells occurred before or after cell proliferation in tumor samples (Raab-Traub and Flynn 1986).

Virus-coded proteins

On infection of B lymphocytes in vitro, EBV establishes a latent type of infection with the expression of a restricted number of viral genes (latent genes) and continued cell survival and division without the production of viral progeny. The characteristics of these latent genes and their products are described below and listed with their alternative names in Table 1; the locations of their open reading frames are shown in Figure 1. This type of infection can be switched to a lytic infection with new virus production and cell death by certain stimuli that induce B-cell activation/differentiation and thereby cause the cell to become permissive for viral replication (Crawford and Ando 1986).

LATENT PROTEINS

The latent gene products include six EBNAs (1, 2, 3A,B,C leader protein (LP)) and three membrane proteins (latent membrane proteins (LMP) 1, 2A, B). In addition, two small RNAs (EBERs 1 and 2) are transcribed by RNA polymerase III but are not translated. The EBNAs initiate from promoters in either the W or the C fragments of the genome as long polycistronic messages which are subsequently spliced to give indivi-

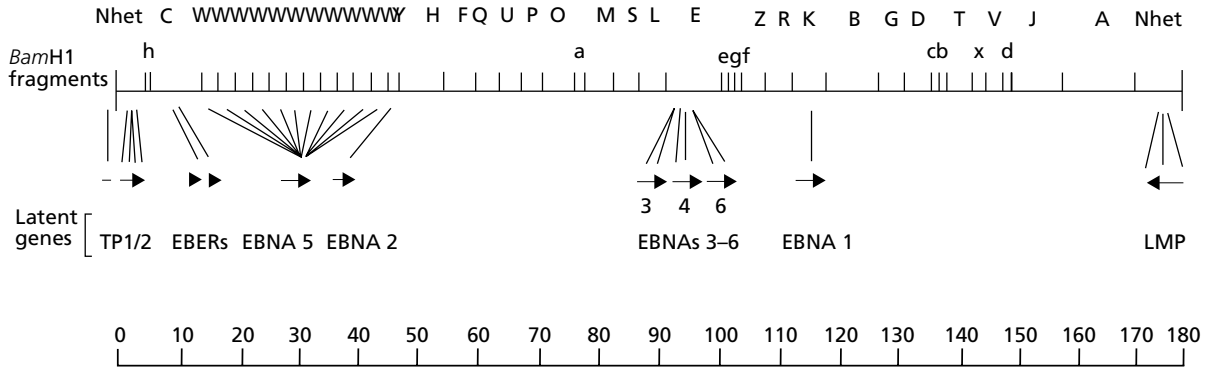

Figure 1 *Linear representation of the Epstein–Barr virus genome.* Bam*HI fragments are shown above and the location of the latent gene open reading frames is shown below. Table 1 *EBV latent genes*

Open reading frame[a]	Gene product	Alternative nomenclature	Mol. wt (kDa)	Cellular location	Required for immortalization	Suggested functions/ properties
BKRF1	EBNA1	–	65–85	Nucleus	+	Plasmid maintenance
BYRF1	EBNA2	–	86	Nucleus	+	Viral oncogene, transactivator of viral and cellular genes
BLRF3–BERF1	EBNA3A	EBNA 3	140–157	Nucleus	+	Viral oncogene, transcriptional regulator
BERF2a–BERF2b	EBNA3B	EBNA 4	148–180	Nucleus	-	NK
BERF3-BERF4	EBNA3C	EBNA 6	160	Nucleus	+	Viral oncogene, transcriptional regulator
BRWF1	EBNA (LP)	EBNA 5	20–130	Nucleus	+/-	Co-activates EBNA2 responsive genes. Increases efficiency of immortalization
BNLF1	LMP1	LMP	58–63	Membrane	+	Viral oncogene, transactivates cellular genes, mimics ligation of CD40
BARF1/ BNRF1	LMP2A	Terminal protein (TP)1	53	Membrane	-	Mimics BCR to enhance B-cell survival, inhibit B-cell activation and entry into lytic cycle
BNRF1	LMP2B	TP2	40	Membrane	-	NK
BCRF1	EBER1, 2	–	–	Cytoplasm/ nucleus	-	Regulation of PKR activity, inhibits apoptosis
BARF0	*Bam*HI A transcripts		–	Cytoplasm	-	NK

BCR, B-cell receptor; EBNA, EB virus nuclear antigen; LMP, latent membrane protein; LP. leader protein; NK, not known; PKR, double-stranded RNA protein kinase.
a) Abbreviated using the *Bam*HI(B) fragment (A–Z) LF or RF for left- or rightward open reading frame (ORF) followed by the number of the gene in a particular ORF.

dual mRNAs. In contrast, the LMPs each initiate from their own promoters. EBNAs 2, 3A,C and LMP1 have been shown by analysis of recombinant mutant viruses to be essential for immortalization, whereas EBNA3B and LP, LMP2A, B and EBERs 1 and 2 are not (for a review see Bornkamm and Hammerschmidt 2001). In addition to these proteins, complex transcripts arising from the *Bam*HI A open reading frame have been demonstrated in latently infected B cells, some of which may be translated into proteins, but their role in the life-cycle of EBV remains unclear (Smith 2001).

EBNA1

EBNA1 is a highly stable, DNA-binding nuclear phosphoprotein that is coded for by the BKRF1 open reading frame. It has a molecular weight ranging from 65 to 85 kDa, the variation being due to the different lengths of the repeat sequences in the molecule. EBNA1 protein consists of about 641 amino acids, is proline-rich, and contains a glycine–alanine repeat sequence; it binds to a specific DNA sequence by the carboxy terminus domain, which is rich in acidic and basic residues. Multiple EBNA1-binding sites occur in the latent viral origin of replication (*oriP*) domain, where the binding of EBNA1 is the only viral factor required for maintenance of the viral episome (Yates et al. 1985). This binding also enhances transcription of EBNA1 and other latent viral genes because it activates the *oriP* enhancer, which regulates the EBNA promoter, Cp, and the LMP promoter (Gahn and Sugden 1995).

EBNA1 binds nonspecifically to metaphase chromosomes, thereby ensuring the equal partitioning of the viral episomes into the two daughter cells at mitosis. Thus EBNA1 expression is a requirement not only for the maintenance of the viral episome in latently infected cells, but also for the synchronization of virus genome replication with cell division.

Mice expressing EBNA1 as a transgene in B cells develop B-cell lymphoma, suggesting a direct role for EBNA1 in B-cell oncogenesis; however, the mechanism involved in this process is unknown (Wilson et al. 1996).

The glycine–alanine domain of EBNA1 inhibits proteosome-mediated degradation of EBNA1 and thereby prevents EBNA1 peptides being displayed on the cell surface bound to MHC class 1 molecules. Thus EBNA1-expressing cells are not recognized by $CD8^+$ cytotoxic T cells (Levitskaya et al. 1995).

EBNA2

EBNA2 is an acidic, nuclear phosphoprotein with a molecular weight of 86 kDa and is coded for by the BYRF1 open reading frame. The protein is a transactivator of viral and cellular genes and is essential for the immortalization of B lymphocytes in vitro (Cohen et al. 1989). EBNA2 does not bind directly to DNA, but interacts with a variety of cellular factors to induce B-cell activation. Three domains of EBNA2 have been identified as essential for immortalization. The acidic activator domain near the carboxy terminus (amino acids 420–464) recruits basal and activating transcription factors (TF) IIB, CBP/p300, TBP, TAF40, and TFIIH, causing transcriptional activation (Johannsen et al. 1995). The second essential domain between amino acids 180 and 337 interacts with the DNA-binding proteins RBP-Jk (also called CBF1), which is ubiquitous, and PU1, which is expressed in a restricted number of hemopoietic cell types, including B cells (Ling et al. 1994; Johannsen et al. 1995). As a result of these interactions EBNA2 transactivates the latent viral genes LMP1, 2A, 2B and the Cp promoter, which gives rise to EBNAs 1, LP, 2, 3A, B, C transcripts. A number of cellular genes, including the oncogenes c-*fgr* and c-*myc* and the B-cell activation molecules CD21 and CD23, are also upregulated by EBNA2. RBP-Jk naturally interacts with the evolutionarily conserved Notch protein signaling pathways, and EBNA2 appears to exploit these in the immortalization process (Hsieh et al. 1997). The third essential domain in EBNA2 is within the most conserved regions of the gene at the amino and carboxy termini, only one of which is required for immortalization. These regions aid the formation of the homotypic and heterotypic associations necessary for EBNA2 to recruit multiple transcription factors (Tsui and Schubach 1994).

The *EBNA2* gene shows considerable DNA sequence diversity between type 1 and 2 EBV, with an overall homology of about 55 percent.

EBNA3A, B, C

These three hydrophilic nuclear proteins are coded for by the BERF open reading frames and clearly arise from a common origin. Their molecular weights range from 140 to 180 kDa, owing to the variable repeat sequences present in each protein. Expression of EBNA3A and C is required for immortalization, whereas that of EBNA3B is not (Tomkinson et al. 1993). All three proteins are transcriptional regulators and bind to RBP-Jk, effectively competing with EBNA2 binding and thereby regulating its function (Zhao et al. 1996). EBNA3A and 3C can repress transcription when targeted to DNA, and have oncogenic activity in cooperation with mutant *ras* (Touitou et al. 2001; Hickabottom et al. 2002).

EBNA-LP

EBNA-LP is a nuclear phosphoprotein that is encoded by the BWRF1 open reading frame, which forms either the leader sequence of the EBNA mRNAs or, by alternative splicing, EBNA-LP mRNA. Because of the DNA repeats in this part of the genome, EBNA-LP protein consists of multiple repeat sequences of 22 and 44 amino acids flanked by unique amino and carboxy termini. Because the DNA repeat sequences vary in number in different virus isolates, the size of EBNA-LP protein varies accordingly. Immunoblotting of EBNA-LP in electrophoretically separated proteins from EBV-infected B cells reveals a ladder of bands differing by 6–8 kDa and corresponding to products of 20–130 kDa, an effect that is probably due to differential splicing of the mRNA.

The function of EBNA-LP is unknown and it is not strictly essential for immortalization, although it increases growth efficiency of infected B cells (Hammerschmidt and Sugden 1989). The protein contains a domain which coactivates gene transcription with EBNA2, and another that inhibits this effect. However, overall EBNA-LP has an activating role which is essential for efficient immortalization.

LMP1

LMP1 is a cytoplasmic and membrane protein that is coded for by the BNLF1 open reading frame. It has a molecular weight of 58–63 kDa and is phosphorylated on serine and threonine residues. The protein associates with the cytoskeleton in the plasma membrane, appearing as discrete patches on staining. LMP1 mRNA is the most abundant viral transcript found in latently infected B cells. The primary amino acid sequence of LMP1 suggests an integral membrane protein with a short 23 amino acid cytoplasmic amino terminus, a large 200 amino acid cytoplasmic carboxy terminus, and six hydrophobic transmembrane segments forming three external loops. A smaller LMP1 mRNA also exists, coding for a protein that lacks the amino terminus of the full-length protein, is expressed in lytically infected cells, and is present in the virus particle.

Full-length LMP1 is a classic viral oncoprotein that is essential for B-cell immortalization (Kaye et al. 1993). Transfection studies using the *LMP1* gene under a heterologous promoter have shown that it induces loss of contact inhibition and anchorage dependence, altered cell morphology, and tumorigenic potential in rodent fibroblasts (Wang et al. 1985). In human EBV-negative B-cell lines and primary B cells, LMP1 induces the changes associated with immortalization. These include an increase in cell size and steady-state calcium levels, upregulation of cell activation and cell adhesion molecule (CAM) expression, as well as upregulation of the cytoskeletal protein vimentin, CD54, and interleukin-6

(IL-6) (Wang et al. 1988). LMP1 expression protects B cells from cell death, probably through induction of the anti-apoptotic protein A20. LMP1 induces cellular genes by activation of the transcription factor NFκB (Hammarskjold and Simurdo 1992) via an interaction with tumor necrosis factor (TNF)-associated cell cytoplasmic factors (TRAFs). Cell activation by this pathway is similar to that of the B-cell surface molecule CD40, which mediates activation on B-cell-receptor engagement by antigen, and LMP1 can partially mimic this function in CD40 knockout mice (Uchida et al. 1999). Studies with LMP1 deletion mutants show that these effects are mediated by the amino terminus of LMP1. Sequencing studies on *LMP*1 genes from EBV isolates from different geographical locations have identified a common 30-bp deletion in the C terminus of LMP1 as well as several point mutations compared to the prototype B95.8 sequence (Hu et al. 1991). This deletion confers increased tumorigenicity in rodent fibroblasts and epithelial cells (Hu et al. 1993), and has been suggested to be more commonly associated with lympholiferative disorders and nasopharyngeal carcinoma than the undeleted form. However, more recent studies show that the incidence of the deletion in tumors reflects the incidence in the general population in each geographical location (Khanim et al. 1996).

LMP2A, 2B

The sequences that make up the LMP2 open reading frame are located at the two ends of the linear EBV genome in BARF1/BNRF1 and are completed only when the genome has circularized to form an episome (Laux et al. 1988). LMP2A and B are produced by alternative splicing of the mRNA, giving rise to proteins of 53 and 40 kDa, respectively. Neither is essential for immortalization of B cells in vitro. Both are hydrophobic membrane proteins with 12 transmembrane segments and 27 amino acid carboxy termini, but whereas LMP2A has 119 amino acids in the amino terminus domain LMP2B has only three. Both LMP2A and B localize to patches in the plasma membrane, and LMP2A colocalizes with LMP1. The amino terminus of LMP2A contains an immunoreceptor tyrosine-based activation motif (ITAM) similar to that found in the B-cell receptor (BCR) molecule, where the phosphorylated motif plays a central role in activation and differentiation processes through its interaction with src and Syk protein tyrosine kinases (PTK). LMP2A associates with these PTKs through its ITAM (Longnecker et al. 1991), and this interaction inhibits calcium mobilization following BCR stimulation of B lymphocytes latently infected with EBV. In this way LMP2A may prevent fortuitous activation of the viral lytic cycle (Miller et al. 1994). LMP2A transgenic mice show abnormal B-cell development, with survival of immunoglobulin negative B cells in peripheral lymphoid tissue (Caldwell et al. 1998). Thus it seems possible that LMP2A can promote B-cell proliferation and survival in the absence of BCR signals, and thereby promote long-term EBV latency in B cells.

The function of LMP2B is not known, but it may play a role in regulating LMP2A function.

EBERs 1 and 2

These two small nonpolyadenylated RNA molecules are coded for by the BCRF1 open reading frame and are the most abundant RNAs in latently infected B cells (10^4–10^5 copies per cell). They are localized mainly in the nucleus, where they bind to the La protein and the large ribosomal subunit protein L22 (Clemens 1994). Although the significance of this complex formation is not known, EBERs show sequence homology to the VA1 and 2 RNAs of adenovirus, which also bind La and are thought to be involved in RNA splicing. EBERs are not required for the in vitro immortalization process or for virus replication (Swaminathan et al. 1991) but, like VA1, bind to and regulate the activity of the protein kinase PKR. This interaction may inhibit the antiviral and antiproliferative effects of interferon, because PKR is induced by, and mediates, interferon activity (Clemens 1994).

Recently EBER expression has been shown to increase the tumorigenicity of Burkitt's lymphoma cell lines by upregulating the expression of Bcl-2 (Komano et al. 1999), but the significance of this finding to BL pathogenesis has not so far been elucidated.

LYTIC PROTEINS

Genes expressed during the EBV lytic cycle have been characterized in LCL that have been induced by various agents (zur Hausen et al. 1978; Luka et al. 1979; Tovey et al. 1978); such genes have extensive homology with those of other herpesviruses. Like other herpesviruses they follow an orderly sequence of expression, each set being activated by the previous set. Lytic genes can be divided into immediate–early genes which are transcribed prior to viral protein synthesis; early genes which are transcribed in the absence of viral DNA synthesis; and late genes which represent the structural proteins and are expressed only after viral DNA synthesis. However, EBV is unique among herpesviruses in possessing a set of latent genes that are already transcribed in infected B cells and may therefore influence subsequent lytic gene expression, although a viral transactivator of the immediate early genes has not been identified among them.

Immediate–early gene products

EBV possesses two genes that can be classified as immediate–early genes: *BZLF1* (Z) and *BRLF1* (R). These two genes code for nuclear proteins which are

DNA sequence specific acidic transactivators and are derived from three mRNA species, one of which contains both R and Z sequences. R and Z coordinately upregulate expression of the early genes by binding to specific sites in the promoter regions. The early promoter elements in the duplication left (DL) and right (DR) regions of the EBV genome, which also include the origin of lytic viral DNA replication (orilyt), contain multiple Z binding sites, and code many early transcripts, including *BHRF1* and *BHLF1* mRNAs.

Z is a DNA-binding protein that shows homology to the DNA-binding domain of the c-*jun* oncogene and binds to AP-1 sites (Farrell et al. 1989). The Z and R promoters (Zp, Rp) contain AP-1 sites and so Z transactivates its own activity as well as that of R. Z interacts with NF-κB and p53 in vivo (Gutsch et al. 1994), and these interactions are thought to inhibit p53-mediated apoptosis during lytic replication and prevent toxic levels of Z accumulating late in the lytic cycle.

Two of the early EBV nuclear proteins (BSMLF1 and BMRF1) may also cooperate in the transactivation of the early genes.

Early gene products

First identified by the staining pattern of sera containing antibodies to EBV when applied to the Raji cell line, which lacks expression of the late genes, the early gene products (early antigens (EA)) were characterized as diffuse (D) (nuclear and cytoplasmic staining) and restricted (R) (nuclear staining) (Henle et al. 1971). It is now known that these complexes consist of approximately 30 proteins, most of which have enzymic functions required for viral DNA replication. Many of these were identified by their homology with early genes from other herpesviruses (Table 2).

Late gene products

Viral capsid proteins This antigen complex (VCA) consists of the nonglycosylated viral structural proteins. They have not yet been analyzed in detail because of the lack of a fully lytic system for EBV in vitro. The major capsid protein is coded for by the BCLF1 open reading frame, other components possibly arising from BNRF1 and BXRF1.

BCRF1 is a gene expressed only late in the lytic cycle that shows ca. 90 percent amino acid sequence homology with the human *IL-10* gene. The protein has been shown to have similar properties to human IL-10, and probably acts to reduce T- and NK-cell responses on initial infection and reactivation in vivo.

EBV glycoproteins The EBV-coded glycoproteins are involved in viral infectivity and spread and show extensive homology with herpes simplex glycoproteins (Table 3). Ten have been identified, most of which are inserted into the membranes of the infected cell, and several become components of the viral envelope (membrane antigens (MA)).

The major viral envelope glycoprotein, gp340/220, is coded for by the BLLF1 open reading frame. The two forms of the protein (molecular weights 340 and 220 kDa) are created by alternative splicing of the mRNA. The protein is found in the Golgi apparatus as well as the plasma membrane of infected cells. The

HSV, herpes simplex virus.

mature protein is heavily *N*- and *O*-glycosylated, about 50 percent of the molecule being carbohydrate. Gp340/220 mediates virus attachment to the B-cell surface by binding to the EBV receptor CR2 (also called CD21) (Nemerow et al. 1987). Thus both naturally occurring and experimentally induced antibodies to gp340/220 prevent infection by blocking attachment.

Gp85 is coded for by the BXLF2 open reading frame and has homology to the herpes simplex virus glycoprotein gH. Gp25 is required for the correct folding, transport to the cell surface and function of gp85. These proteins are localized to the plasma membrane and viral envelope, where they form a trimolecular complex with gp42. Gp42 is coded for by the BZLF2 open reading frame and is involved in penetration of the virus through the cell membrane during B-cell infection by its binding to HLA class II molecules on the B-cell surface. This glycoprotein is not required for viral entry into epithelial cells that are HLA class II negative (Borza and Hutt-Fletcher 2002).

Gp110 is coded for by the BALF4 open reading frame and has homology with the herpes simplex virus glycoprotein gB. It is *O*- and *N*-glycosylated and is localized to the nuclear and cytoplasmic membranes of infected cells. Gp110 has an important role as a virulence factor; high levels of expression can determine infection of cells other than B lymphocytes (Neuhierl et al. 2002).

Immortalization

Binding of EBV to B lymphocytes occurs through a ligand–receptor interaction between the major viral envelope glycoprotein gp340/220 and the cell surface complement receptor molecule CR2 (CD21) (Nemerow et al. 1987). CR2 is a member of the immunoglobulin superfamily and is expressed on all mature circulating B lymphocytes. It forms part of a signal transduction complex including CD19, TAPA1, and Leu-13 (Bradbury et al. 1992); it is postulated that the binding of EBV to CR2 induces initial B-cell-activating signals, but these have not yet been clearly defined. Once bound, the trimolecular complex of gp85, 42, and 25 on the viral envelope initiate fusion with the cell membrane, releasing the capsid into the cytoplasm. The viral genome rapidly enters the cell nucleus where it circularizes to form an episome, which later amplifies to give multiple copies per cell.

EBNAs 2 and LP, originating from the W promoter (Wp), are the first virus-coded proteins to be detected, at around 12–15 h post infection. EBNA2 protein then generally initiates a promoter switch from Wp to Cp (Woisetschlaeger et al. 1991) by complexing with RBP-Jk at the EBNA2 response element upstream of Cp, thereby allowing expression of all the EBNA proteins by 24 h. EBNA and LP also upregulate the LMP promoters, so that full latent viral gene expression is achieved by 48 h post infection.

Cell enlargement and activation with the expression of the B-cell activation marker CD23 occur at around 48 h post infection and can be attributed mainly to the action of LMP1 (Wang et al. 1990). By 72 h some cells have progressed through the G_1, S, and G_2 phases of the cell cycle and are entering mitosis. The cells then continue to cycle indefinitely, giving rise to an immortalized LCL.The phenotype of cells in an LCL is similar to thatof antigen-stimulated lymphoblasts, with the expression of the B-cell-activation markers typical of this stageof B-cell differentiation (e.g. CD23, CD39, CD30, CD70, ki24) as well as the CAMs, CD11a, CD54, and CD58.

A few cells in an LCL (0–5 percent) enter the lytic cycle, a switch that seems to be triggered by physiological stimuli such as differentiation of the cell (Crawford and Ando 1986), and which can be induced by B-cell-activating agents such as phorbol esters (zur Hausen

et al. 1978), sodium butyrate (Luka et al. 1979), and anti-immunoglobulin (Tovey et al. 1978). Cells of LCLs are immortal but cytogenetically normal. They are not, by definition, transformed cells because they do not form colonies in soft agar or give rise to tumors in nude mice (Nilsson et al. 1971). These characteristics differ from those of EBV-carrying cell lines derived from BL biopsy material (see EBV gene expression).

EBV replication

The induction of the lytic cycle in B lymphocytes or squamous epithelial cells infected in vitro is associated with differentiation of the cell (Crawford and Ando 1986; Kirimi et al. 1995), suggesting that the availability of cellular transcription factors determines the outcome of infection. In addition, the lytic cycle can be activated by transfection of the *BZLF1* gene or superinfection with the P3HR1 strain of virus, which contains defective virus in which *BZLF1* is adjacent to Wp (Miller et al. 1984).

Replication of EBV DNA begins at the origin of lytic replication, which is 1.4 kb in length and contains many inverted repeat sequences (Hammerschmidt and Sugden 1988). *ori*lyt acts as an amplicon, giving rise to many linear concatemers of the genome by the rolling circle method, and EBV-coded DNA polymerase is required for this process. The terminal repeat elements are required for cleaving and packaging the newly formed virions.

EBV gene expression

Infection of B lymphocytes in vitro leads to initiation of transcription of the polycistronic EBNA mRNA from Wp with an EBNA2-induced switch to Cp after 48–72 h (Woisetschlaeger et al. 1991). This results in expression of all the EBNA proteins as well as expression of the three latent membrane proteins from their own promoters. In addition, EBERs and *Bam*H1 A transcripts are detectable, and this gene expression pattern is termed full latent gene expression, or latency type III (Rowe et al. 1992). However, in vivo, other patterns of viral gene expression have been identified. In BL cells, which are small, nonactivated cells expressing the cellular markers of a germinal centre B cell (CD10, CD77), only EBNA1 protein, EBERs and *Bam*H1 A transcripts are detected (latency type I) (Rowe et al. 1986). The EBNA1 mRNA initiates from a promoter in the Q region of the genome (Qp). Wp and Cp are silent and have been shown to be methylated (Masucci et al. 1989). However, when BL cells are cultured, demethylation often occurs, associated with a drift to full latent viral gene expression and a lymphoblastoid phenotype (Rowe et al. 1987).

An alternative pattern of transcription (latency type II) is seen in Reed–Sternberg cells in EBV-positive Hodgkin's disease (Deacon et al. 1993) and the malignant epithelial cells of nasopharyngeal carcinoma (Brooks et al. 1992). Here EBNA1 is expressed from Qp, and LMP1 and 2 are also expressed in the absence of the EBNAs. EBERs and the *Bam*H1 A transcripts are again detectable (Table 4).

Viral gene expression in circulating latently infected memory B cells in vivo is a controversial issue, as RT-PCR is the only technique with sufficient sensitivity to detect these rare cells. This technique does not give an indication of the genes expressed in individual cells or determine whether translation to protein occurs; however, the most regularly detected transcripts are EBERs and LMP2.

CLINICAL AND PATHOLOGICAL ASPECTS

INTRODUCTION

As a very ancient parasite of humans, EBV has established a delicately balanced relationship with its host that is almost entirely benign under normal conditions. Natural primary infection is usually inapparent, and is always followed by a lifelong, silent carrier state that becomes manifest as disease only if the virus–host balance is disturbed (Table 5).

EPIDEMIOLOGY

EBV is found in all human populations and, under natural conditions, primary infection occurs in early

Table 4 *Latent viral gene expression in EBV-associated tumors*

	EBNA						LMP				
Tumor	1	2	3A	3B	3C	LP	1	2A	2B	EBERs	EBNA promoter usage

EBNA, EB viral nuclear antigen; EBERs, EB virus-coded small RNAs; LMP, latent membrane protein; LP, leader protein.

Table 5 *Conditions associated with EBV infection in humans*

Condition	Occurrence
Clinically silent childhood primary infection	Universal in developing countries; common in developed countries
Delayed primary infection (teenagers/young adults)	Seen in developed countries: ca. 50% are clinically silent, as in childhood, ca. 50% have acute infectious mononucleosis – usually resolves; may become chronic
Primary infection with fatal outcome	Very rare familial X-linked lymphoproliferative disease (Duncan syndrome)
Lymphomas in immunodepression	In organ graft recipients
	In AIDS patients
Oral hairy leucoplakia	In AIDS patients and other T-cell immunodeficiencies
Endemic Burkitt's lymphoma	Common in children where falciparum malaria is hyperendemic
Nasopharyngeal carcinoma	Common in south Chinese and Inuit adults
Hodgkin's disease	Developed countries: *ca*. 50% are EBV associated. Developing countries: <90% EBV associated
Tumors with tenuous or suspected links to EBV infection	Some T-cell lymphomas, leiomyosarcomas, salivary gland cancers, undifferentiated carcinoma of the stomach

childhood; thus, in developing countries, 99.9 percent of all children are infected by 2–4 years of age, depending on geographical region. However, in industrialized countries with high standards of hygiene a considerable number of people do not become infected as young children, the percentage of each age group remaining free of infection as teenagers or young adults depending in western societies on socioeconomic status: the higher the standard of living, the greater the percentage (Henle and Henle 1979b). Among the very affluent as many as 50 percent of young adults may never have been infected.

Primary infection in early childhood is symptom-free and leads only to the generation of antibodies to the viral and virus-determined antigens (Henle and Henle 1979b) and to the development of specific cytotoxic T lymphocytes (Murray et al. 1992). These humoral and cellular immunological responses are maintained continuously thereafter and are responsible for keeping the lifelong EBV infection in check; the virus persists as a latent infection in a few circulating B lymphocytes (Lewin et al. 1987) and as a productive infection somewhere in the mouth and pharynx, the urogenital tract and, perhaps, the salivary glands. EBV is shed into the buccal fluid in readily detectable amounts in about 20 percent of those who have been infected, and in small amounts from time to time in many of the remainder (Yao et al. 1985); the virus has also been detected in genital secretions (Sixbey et al. 1986; Israele et al. 1991). The nature of the permissive cells producing infectious virions in the oro- and nasopharynx was for long a continuing controversy (Allday and Crawford 1988; Niedobitek and Young 1994): was the virus coming from squamous epithelial cells or from intraepithelial B lymphocytes? Evidence suggesting that it might only be the latter has recently emerged because in the absence of lymphocytes, as occurs in patients with X-linked agammaglobulinemia, EBV infection does not seem to take place (Faulkner et al. 1999). However, even if this observation appears to indicate that EBV does not normally infect and replicate in squamous epithelial cells of the mouth and pharynx, doubts and problems remain; squamous epithelial cells become infected in several conditions and an explanation of how and why the virus infects them is still required. Furthermore, such cells are capable of virus production; the latent EBV infection always carried by the malignant epithelial cells of nasopharyngeal carcinoma can be activated in vitro into a replicative cycle (Trumper et al. 1976), with release of infectious virus (Trumper et al. 1977), and virions are regularly produced in the squamous epithelial cells of oral 'hairy' leukoplakia (Greenspan et al. 1985).

Nevertheless, it has been clear for a great many years that virus in the buccal fluid is the main source of transmission of the infection in the population, by droplets and casually contaminated objects in the case of young children, and by direct salivary transfer during kissing among the sexually active (Hoagland 1955).

Those who miss the clinically silent natural primary infection in childhood are likely, sooner or later, to undergo delayed primary infection. Although 50 percent of such delayed infections are symptom-free, as in childhood, the other 50 percent are accompanied by disease: classic infectious mononucleosis (IM) (Sawyer et al. 1971; Hallee et al. 1974).

CLINICAL MANIFESTATIONS

Infectious mononucleosis

The fact that it is the teenagers and young adults in the upper classes of western countries who tend to escape silent infection as children makes IM predominantly a disease of the most affluent groups, and causes it to be exceptionally rare in developing countries. Although most cases of IM occur in adolescents and young adults,

older children and the middle-aged may occasionally develop the disease as a consequence of primary EBV infection, and rarely also the elderly. IM has long been known to be associated with kissing among young people (Hoagland 1955), and the pattern of acquisition results from a healthy carrier who is shedding virus in his or her saliva passing this during close buccal contact directly into the oropharynx of a partner who has not been primarily infected in the usual way as a child. This method of spread explains why case-to-case infection and epidemics are not seen with IM, and why the incubation period – perhaps 30–50 days – is difficult to calculate. Primary EBV infection giving IM-like symptoms may also be transmitted by blood transfusion (Gerber et al. 1969) or organ grafting (Haque et al. 1996) from an infected donor to a previously uninfected recipient.

SYMPTOMS AND SIGNS

There may be vague prodromal indisposition or an abrupt onset with sore throat, fever and sweating, anorexia, headache, and marked malaise. Brief dysphagia and orbital edema may be noticed. Severe edema of the tonsils and pharynx can sometimes cause pharyngeal obstruction. Erythematous rashes occur in a small number of untreated patients, but affect most of those who have been taking ampicillin. The pharynx, fauces, soft palate, and uvula are red and swollen, and may develop a greyish exudate. Generalized lymphadenopathy is almost invariable, most marked in the cervical region, with symmetrical, discrete, slightly tender glands; splenomegaly is seen in 60 percent of cases, an enlarged liver in 10 percent, and actual jaundice in about 8 percent. Crops of palatal petechiae are found in about one-third of patients. If mild, IM may resolve in days, but usually continues for 1–2 weeks, and is often followed by a period of marked lethargy before complete recovery. The length of convalescence may be influenced by psychological factors, but about one case in 2 000 continues in a truly chronic or recurrent form for several months or even years; exhaustive investigation of such patients has sometimes revealed minor immunological defects (Virelizier et al. 1978).

In contrast, an extremely rare genetically determined, X-linked lymphoproliferative condition (XLP disease or Duncan syndrome) first described by Bar et al. (1974) is due to a specific inability to respond normally to EBV during primary infection, and the affected young males of certain kindred die from IM owing to progressive destruction of vital organs and multisystem failure (Gaspar et al. 2002). The gene for XLP syndrome has now been cloned (Coffey et al. 1998; Sayos et al. 1998); it lies on the long arm of the X chromosome and codes for a protein responsible for controlling normal T-cell activation. Because the gene is mutated in XLP syndrome cases, failure of this control probably permits the cytotoxic T cells generated by primary EBV infection to extend their action from the true targets provided by EBV-infected B cells to include the destruction of normal cells of the patient's vital organs (Howie et al. 2000).

COMPLICATIONS

Serious but rare complications include secondary bacterial throat infections, traumatic rupture of the enlarged spleen, asphyxia from pharyngeal edema, massive hepatic necrosis, Guillain–Barré syndrome, and autoimmune manifestations such as thrombocytopenia and hemolytic anemia (Finch 1969).

PATHOGENESIS

The very long evolutionary association of EBV with its human host (more than 35–45 Myr) has ensured that it can establish an inapparent infection in early childhood which thereafter persists for life (Henle and Henle 1979b). When delayed primary infection occurs as a result of the high living standards of modern western countries, young adults encounter the virus for the first time at an age when the mode of infection and size of infecting dose are different from those in children: children come into contact with saliva from a shedder as airborne droplets or contamination on some sucked object, and thus receive a much smaller amount of virus than a young person taking in large quantities of virus-containing saliva from such a carrier during mouth-to-mouth kissing (Hoagland 1955). An exaggerated immunological response to a very large infecting dose of EBV fits well with the changes of IM: large numbers of activated $CD8^+$ T cells stimulated by a mass of infected B cells (expressing all the known latent viral genes) in the circulation, in lymph nodes, tonsils, lymphoid tissue of the mouth and pharynx, spleen, liver, and elsewhere. These T cells kill EBV-infected target cells (Callan et al. 1998), secrete multiple lymphokines (Foss et al. 1994), and are thus the cause, by immunopathological mechanisms, of the sore throat, fever, malaise, lymphadenopathy, and hepatosplenomegaly.

IMMUNE RESPONSES AND DIAGNOSIS

During acute IM, serum IgM and IgG antibodies to VCA and IgG anti-EA antibodies appear early, whereas anti-EBNA1 antibodies are not usually detectable until convalescence (Henle and Henle 1979b). On recovery, IgM anti-VCA and IgG anti-EA disappear but IgG antibodies to VCA and EBNA1 are maintained for life (Figure 2) (Henle and Henle 1979a).

Because it is not usually possible to document seroconversion, the presence of IgM antibodies to viral capsid antigen provides the most reliable diagnostic test. This may be corroborated by finding anti-EA antibodies (usually of D type) or the absence of antibodies to EBNA1, or both (Henle and Henle 1979a). These tests

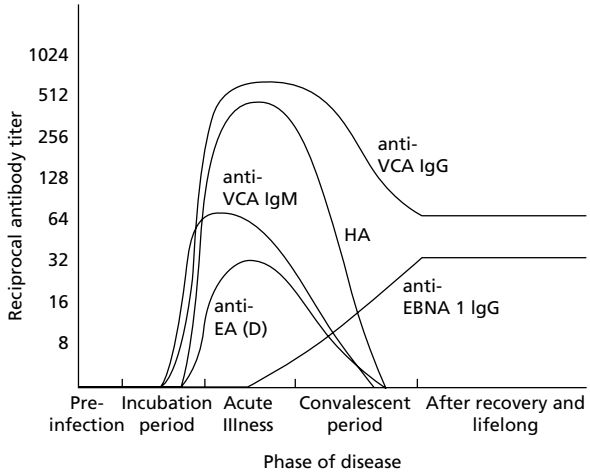

Figure 2 *Epstein–Barr virus-specific antibody response in infectious mononucleosis. Typical serum antibody titers as assessed by indirect immunofluorescence are indicated. EA (D), early antigen (diffuse); EBNA, EB viral nuclear antigen; HA, heterophile antibody; VCA, viral capsid antigen.*

depend on immunofluorescence staining of B-cell lines expressing viral antigens, are time-consuming, and are usually carried out only in larger laboratories. A number of commercial ELISAs are available but they lack the sensitivity of immunostaining. The rapid screening Monospot test is more widely used; this has been adapted from the earlier Paul–Bunnell test for IgM heterophil antibodies which agglutinate red cells from nonhuman sources. Although the heterophil antibodies are not directed against viral-coded antigens they are present in up to 85 percent of IM sera, but it must be remembered that cases of Monospot-negative IM are frequent outside the classic 15–25-year age range, and false positives may occur in pregnancy and autoimmune disease (Okano et al. 1988). An additional diagnostic feature of IM is the presence of a lymphocytosis of up to 15×10^9/l, most cells having an 'atypical' morphology. The clinical and hematological findings and a positive Monospot test give a reliable diagnosis, but if the latter is negative, tests for IgM anti-VCA antibodies must be done. Retrospective diagnosis may be possible if suitable samples are available to allow seroconversion to, or a rising titer of, EBNA1 IgG antibody to be detected.

Endemic ('African') Burkitt's lymphoma

Classic BL (Burkitt 1963) is a B-cell tumor found in parts of Africa and Papua New Guinea, where the temperature does not fall below 16.5°C or the annual rainfall below 55 cm (Burkitt 1970a). BL is overwhelmingly a disease of children, and is extremely rare over the age of 14 years. In endemic areas it is more common than all other childhood cancers added together. There is no evidence in the tumor belt for any tribal or racial susceptibility (Burkitt 1963). Endemic BL is distinct from the 'Burkitt-like' tumors (sometimes called 'American' or 'sporadic' BL) seen sporadically everywhere in the world, which have a different age incidence, anatomical distribution and response to therapy. The term 'Burkitt type' is sometimes also applied to certain leukemias because of morphological resemblances of the malignant cells.

Some 97 percent of endemic BL carries the EBV genome, whereas only 12–25 percent of the sporadic tumors are EBV-positive (Ziegler et al. 1976); it would seem that the 3 percent of EBV-negative BLs occurring in endemic areas are in fact sporadic BLs that occur at low incidence worldwide.

The association between EBV and endemic BL is so close that it is now generally accepted that the virus is a necessary (albeit not solely sufficient) element in causation of the disease. It is an essential link, together with cofactors, in a complicated chain of events that leads to the malignant change (Epstein and Achong 1979). BL cells contain the EBV genome, but only EBNA 1 is expressed. Hyperendemic falciparum malaria is an important cofactor, and its spread by anopheline mosquitoes that require warmth and moisture explains the climate dependence of the tumor (Burkitt 1969).

SYMPTOMS AND SIGNS

The tumor is usually multifocal, occurs in a variety of sites, and the symptoms depend on the anatomical location of the lesions (Burkitt 1963). Tumors in the maxilla or mandible are present in 70 percent of patients and are the presenting feature of most of these (Figure 3). They may be multiple in two, three or even all four

Figure 3 *A 9-year-old girl with a typical Burkitt's lymphoma of the right upper maxilla presenting through the orbit. The Epstein–Barr virus was first identified in cultured malignant lymphoblasts from this tumor.*

quadrants of the jaws, and are almost always accompanied by tumors elsewhere. A rapidly growing mass, loosening of teeth, and exophthalmos due to orbital spread are the main consequences. Abdominal tumors are also common, involving retroperitoneal nodes, liver, ovaries, intestine, and kidneys. BL may present in the thyroid, the adolescent female breast, the testicles, the salivary glands, and the skeleton. Extradural spinal tumors cause paraplegia of rapid onset. An unusual and characteristic feature of this lymphoma is its failure to involve the spleen and the peripheral lymph nodes.

Clinically, the tumors are firm, very rapidly growing, and painless; even when large, they cause minimal constitutional disturbance. The clinical signs are determined by the tumor sites, but wherever these may be BL grows relentlessly and, in the absence of treatment, death ensues within a few months (Burkitt 1963).

PATHOGENESIS

Molecular biological investigations are successfully unraveling the sequence of EBV gene expression that enables the virus to immortalize normal human B lymphocytes in vitro into continuously growing cell lines. Explanations are also beginning to emerge as to how the viral genes, in combination with cofactors, can bring about the malignant change leading to BL. There are currently two possibilities:

- EBV infection in the presence of the impaired immunological control brought about by hyperendemic malaria leads to a high level of EBV-driven B-cell proliferation, perhaps by similar mechanisms to in vitro immortalization; this proliferation in turn increases the chances of one or another of three BL-specific chromosomal translocations (t8:14; t8:22; t2:8) occurring, each of which can deregulate the c-*myc* oncogene on chromosome 8 by bringing it under the influence of an immunoglobulin gene promoter on chromosomes 14, 22, or 2. This deregulation causes malignant change in the affected cell and the rapid outgrowth of a clone of tumor cells (Klein 1987).
- The chronic immunological stimulation of hyperendemic malaria generates a high turnover of pre-B cells in the bone marrow; one or more of these early lymphocytes acquires one of the three chromosomal translocations involving c-*myc* deregulation by an error occurring during immunoglobulin gene rearrangement, and this renders the affected cell responsive to growth signals; infection of such a cell by EBV finally provides viral functions conferring malignancy and a tumor clone grows out (Lenoir and Bornkamm 1987).

However, with either possibility the virus–host balance is disturbed by hyperendemic malaria, and additional molecular explanations continue to emerge (Farrell et al. 1991, Kelly et al. 2002).

IMMUNE RESPONSES AND DIAGNOSIS

In the appropriate geographical regions endemic BL can often be diagnosed on clinical grounds, but this should be confirmed by histological examination of a biopsy specimen. In addition, antibodies to EBV antigens have a unique pattern in BL: titres rise as the disease progresses and fall as tumors regress in response to treatment. These changes may be used to assess disease outcome. IgG antibodies to VCA are found at 8–10 times higher geometric mean titers than in healthy controls matched for age, gender, and residence. IgG antibodies to EA-R and MA are also detectable (Henle et al. 1969), and likewise vary with disease progression; successful treatment causes a rise in anti-MA and a fall in anti-EA-R, whereas the reversal of this pattern usually heralds a recurrence of the tumor.

THERAPY

Surgery and radiotherapy are not effective, but excellent results are obtainable with moderate courses of chemotherapy (Burkitt 1970b). Cyclophosphamide is the drug of choice, and dramatic and sustained resolution is not uncommon when tumors are small.

Lymphomas in immunosuppressed individuals

The lifelong EBV infection present in all normal seropositive individuals is controlled by cell-mediated immune mechanisms. In primary and secondary suppression of cellular immunity this control of persisting EBV infection is lost, leading to increased virus replication in the oral cavity, increased numbers of virus-carrying B lymphocytes in the circulation, and increased levels of serum antibodies to lytic-cycle EBV antigens (VCA, EA). When this occurs it is sometimes described as a 'reactivated infection', although the condition is clinically silent. However, on occasions the loss of control results in EBV-associated lymphoproliferative disease. This type of disease also occurs when immunosuppressed individuals undergo primary infection and fail to mount the normal immunological response to the virus (Thomas et al. 1991).

ORGAN GRAFT RECIPIENTS

It has long been known that organ graft recipients who receive lifelong immunosuppressive drugs to prevent graft rejection have an increased risk of developing lymphoproliferative disease and lymphoma (28–100 times that of normal controls) (Penn 1983). Most of these conditions, known as post-transplant lymphoproliferative disease (PTLD), are of B-cell origin, contain the EBV genome, and express viral antigens in their cells. Lymphoproliferative disease has two forms of clinical presentation. In about 50 percent of cases it occurs within the first year after transplantation, in a young age

group, has IM-like symptoms, and is associated with primary EBV infection in patients who were seronegative at the time of grafting. The second type of presentation occurs in older patients late after transplantation, and takes the form of a localized mass, commonly in the gut, central nervous system, or transplanted organ (Hanto et al. 1981, 1985). Biopsy of the lesion reveals large-cell lymphoma, which is usually monoclonal in origin, although progression from a polyclonal B-cell proliferation probably occurs early in the disease (Frizzera et al. 1981, Frizzera 1987). The fact that all the EBV latent viral genes are expressed in these lymphoproliferative diseases, just as with lymphoblastoid cell lines immortalized by the virus in vitro, suggests that EBV is of prime importance in the etiology of the lesions (Thomas et al. 1990), although other events – perhaps cytogenetic abnormalities – may be necessary to cause the monoclonal growth.

Reduction of immunosuppressive drugs, with or without acyclovir therapy, has caused complete and often sustained regression of the tumors in many cases (Starzl et al. 1984). This has therefore become the first line of treatment, cytotoxic drugs and/or radiotherapy being used only when there is no response or after recurrence. EBV-specific cytotoxic T cells grown in vitro have been given after bone marrow transplantation to protect against such EBV-driven lymphoproliferation prior to regeneration of the immune system (Rooney et al. 1995), and to treat PTLD in bone marrow and solid organ transplant recipients (Haque et al. 2002).

AIDS PATIENTS

Two types of lymphoma are seen with increasing frequency in AIDS patients: large-cell lymphoma and Burkitt's lymphoma. Both of these may be associated with EBV (Kalter et al. 1985).

Large-cell lymphomas similar to those seen in organ graft recipients occur in severely immunocompromised AIDS patients; their distribution is extranodal and involves many unusual sites, the most common being the central nervous system. These lymphomas have a strong association with EBV, which reaches 100 percent in cerebral tumors (Herndier et al. 1994). The clinical presentation depends on the site involved, but the progression is rapid, with a mean survival time from diagnosis of 3–4 months. The treatment of choice is radiotherapy, although the results are disappointing, mainly because patients in the terminal stages of the underlying AIDS are in such poor general condition.

Burkitt's lymphoma occurs earlier in the course of human immunodeficiency virus (HIV) disease, while the immune system is still relatively intact, and is therefore more amenable to treatment. About 50 percent of these lymphomas contain EBV DNA.

Hodgkin's disease

There has long been a suspicion that EBV may play some part in the induction of Hodgkin's disease (HD) because of the similar socioeconomic epidemiology of HD and IM, and because of the well established fact that within 5 years of IM there is a four- to sixfold increase in the likelihood of developing HD (Mueller et al. 1989). In recent years, evidence has been obtained that about 60 percent of HD is EBV associated, and this mainly involves the mixed cellularity type. However, surprisingly, the majority of EBV-associated mixed cellularity HD cases do not occur in the post-IM age group (Jarrett 2002).

In EBV-associated HD EBV DNA is carried and viral proteins expressed (latency II) in Reed–Sternberg and the tumor reticulum cells (Weiss et al. 1989; Herbst and Niedobitek 1994), and both these cell types are now known to be of germinal center B-cell origin (Marafioti et al. 2000). These intriguing findings appear to implicate EBV in certain types of HD.

T-cell lymphomas

EBV DNA has been detected with varying frequency in different types of T-cell lymphoma. Detection rates of up to 97 percent have been recorded in angioimmunoblastic lymphadenopathy (Ott et al. 1992), 84 percent in nasal lymphoma (previously called midline granuloma) (Harabuchi et al. 1990), and in 46 percent of peripheral T-cell lymphoma (Jones et al. 1988). In addition, sporadic cases of EBV-positive angiocentric T-cell lymphoma and of T-cell lymphoma related to immunosuppression and chronic EBV infection also occur. In these lesions the cell phenotype is usually that of clonal, mature T cells, which more often express the CD4 than the CD8 marker. The EBV gene expression is usually of the latency II type, but the latency III pattern has also been recorded.

Although it is now clear that EBV can infect T cells under certain conditions, the involvement of the virus in the pathogenesis of T-cell lymphoma remains to be elucidated.

Various other malignancies

Recent reports have linked EBV to various cancers, including some thymic epithelial tumors (Leyvraz et al. 1985; Wu and Kuo 1993), some undifferentiated salivary gland carcinomas (Hamilton-Dutoit et al. 1991) and, more regularly, to several types of gastric carcinoma (Takada 2000); surprisingly, smooth muscle tumors carrying EBV have also been reported in immunosuppressed children (Lee et al. 1995; McClain et al. 1995). Little is known about the EBV gene expression in any of these tumors, and further work is required before a definite association can be established.

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma (NPC) arises from the squamous epithelial cells of the postnasal space; primary tumors are not found outside this well-defined anatomical site. About 70 percent of NPC are undifferentiated in type; the remainder show squamous differentiation. The tumor occurs rarely throughout the world, but has a very high incidence in southern Chinese wherever they live, and in the Inuit and related races of North America and Greenland. Among populations with a high incidence, NPC is the most common cancer of men and the second most common of women. There is also a high incidence of NPC in Malays, Dyaks, Indonesians, Filipinos, and Vietnamese, and a moderately raised incidence in a belt across North Africa, down through the Sudan and into the Kenyan Highlands. Comprehensive reviews have been given by Shanmugaratnam (1971, 1978). The tumor is usually a disease of middle or old age, except that in medium–high incidence areas of Africa it has bimodal age peaks, the first involving children and young people under 20 years of age (Cammoun et al. 1974), and a second affecting much older people. The tumor cells of undifferentiated NPC always carry the EBV genome (Klein 1979; Niedobitek et al. 1991), and most authorities agree that the virus plays a role in causation as a necessary but not the sole element in the etiological complex.

SYMPTOMS AND SIGNS

About two-thirds of patients present with one or more symptoms caused by the local effects of the tumor: nasal obstruction, discharge or bleeding; deafness, tinnitus, or earache; ocular paresis from tumor spread to affect cranial nerves. The remaining third complain only of cervical lymph node enlargement due to metastatic spread from a primary tumor that is frequently occult. The signs result either from local tumor spread, causing soft tissue distortion around the postnasal space or cranial nerve palsies, or as a consequence of lymphatic spread to cervical and later supraclavicular lymph glands, which become hard and fixed. Bloodborne metastases may be in any organ but are frequent in bones, liver, and lungs, the signs depending on the organ involved (Shanmugaratnam 1971).

PATHOGENESIS

Little is known of EBV gene function in normal infected epithelial cells, but viral gene expression in the malignant cells of NPC is well characterized; although restricted, it is less so than in BL cells with EBNA1 detected in every tumor cell of undifferentiated NPC and LMP1 in a variable proportion (latency type II) (Young et al. 1988). In addition to the virus, racial predisposition plays a role, and, among southern Chinese, a modest genetic predisposition has also been demonstrated (Simons et al. 1974; Chan et al. 1983). Environmental cofactors associated with the Chinese way of life have emerged from studies on migrants (Buell 1974; Henderson 1974), and two likely candidates have been identified:

- Traditional herbal remedies (taken as snuff) made from dried plants of the *Euphorbiaceae* and *Thymeliaceae* families, which contain tumor-promoting phorbol esters (Hirayama and Ito 1981).
- Traditional salt fish dishes, which contain carcinogenic nitrosamines (Huang et al. 1978).

Because EBV replicates in the nasopharynx of all carriers, and because southern Chinese always undergo primary infection as very young children (Henle and Henle 1979b), the taking of snuffs containing phorbol esters is significant because these chemicals are also powerful activators of EBV replication (zur Hausen et al. 1979) as well as having tumor-promoting effects. Thus, if virus production is greatly increased in people with a genetic predisposition to NPC, there will be an unusually large pool of EBV-infected cells that might progress to malignancy, perhaps through a combination of EBV *LMP1* oncogene function with nitrosamine carcinogenicity and phorbol ester tumor-promoting effects.

IMMUNE RESPONSES AND DIAGNOSIS

The diagnosis of NPC is usually made histologically on a biopsy sample from the primary tumor or from an enlarged cervical lymph gland. In addition, serum antibody titers show a characteristic and specific pattern of reaction, regardless of geographical location, and can therefore be used for diagnosis; IgG and IgA antibodies to VCA and EA-D are raised, and IgA against these antigens can be found in the saliva (Klein 1979). In the high incidence areas of southern China, mass screening of susceptible populations for serum IgA antibodies to VCA has been successful in detecting very early cases of NPC (Zeng et al. 1982), an important achievement because such early lesions usually respond very well to treatment.

THERAPY

The treatment of choice is radiotherapy, which gives 5-year survival rates of 60 percent or more in the earliest stages of the disease. Of those who survive, 70 percent remain permanently free of relapse (Ho et al. 1983). More advanced stages have correspondingly worse prognoses.

Oral hairy leukoplakia

This unusual condition is seen fairly frequently in HIV-positive homosexual men, often before AIDS develops, but sometimes heralding or accompanying the onset of

clinical AIDS. Painless white patches occur on the tongue and/or the lateral buccal mucosa; the lesions are usually multiple, measure up to 3 cm in diameter, are slightly raised, and have a 'hairy' or corrugated surface (Greenspan et al. 1985).

The squamous epithelial cells affected by this condition contain large amounts of actively replicating EBV (Greenspan et al. 1985). Acyclovir arrests the virus replication and the lesions regress, but only for the period during which drug treatment is continued.

VACCINES AGAINST EBV

In the mid-1970s evidence linking EBV to some causative role in endemic BL and NPC was sufficiently strong to warrant the suggestion that vaccine prevention of the virus infection might be a way of decreasing the incidence of the associated cancers in high-risk populations (Epstein 1976). Although BL is of outstanding importance as a model for human viral carcinogenesis, and is exceedingly common in endemic areas, in terms of world cancer it is insignificant; however, NPC is a major oncological problem for very large populations, justifying efforts to control it through the development of a vaccine against EBV. Vaccine protection against IM would also be useful.

An extended program of work on an MA-based anti-EBV vaccine (Epstein 1986, 1994) succeeded in establishing that the purified gp340 component of MA induced virus-neutralizing antibodies, and indeed cytotoxic T-cell responses (Wilson et al. 1999), on injection into cottontop tamarins. Furthermore, the latter – the only animal known to respond with lesions to experimental EBV infection – when immunized in this way were protected against a 100 percent carcinogenic challenge dose of virus (Epstein 1986, 1994). Recently, gp340 purified from cultures of mammalian cells into which the *gp340* gene had been engineered (Jackman et al. 1999) was used in a successful phase I trial in human volunteers (Gilbert 1999). A phase II trial subsequently conducted for a major pharmaceutical company in a larger group of volunteers has given preliminary results that show some encouraging protective effects (Bollen 2002); a phase II placebo-controlled trial is currently in progress.

Other approaches are also going forward. Recombinant vaccinia viruses expressing gp340 have been made, and a small scale vaccination experiment using this in nine Chinese children has given some evidence of protection (Gu et al. 1995), but a wildtype strain of vaccinia was employed for the construct which would not be acceptable for general application. A quite different project has sought to induce specific cytotoxic T-cell immunity, not antibodies: selected EBV epitopes have been fused together in a synthetic polyepitope protein for injection, not to prevent infection, but to limit EBV replication after infection by destruction of virus-producing cells by the stimulated T cells, and thereby perhaps decrease disease manifestations. Preliminary trials to explore this technique in volunteers have begun (Khanna et al. 1999).

INTRODUCTION

The molecular aspects of poxvirus replication are considered in Poxvirus replication. This chapter considers the origin of vaccinia virus and its use to eradicate smallpox, the classification and phylogenetic relationships of poxviruses, how these viruses are transmitted and cause disease in their hosts and how they may be controlled. Lastly, the potential use of poxviruses in bioterrorism is discussed.

WHAT IS A POXVIRUS?

Poxviruses are large viruses that have double-stranded DNA genomes $\geqslant$135 kb. The virions are large and complex, are surrounded by a lipid envelope and lack icosahedral or helical symmetry. Unlike most DNA viruses, poxviruses replicate in the cell cytoplasm and therefore encode the great majority of the proteins needed for their transcription and DNA replication. Poxviruses also encode many virulence factors that are nonessential for virus replication in cell culture, but help the virus to survive in its particular host(s). These viruses infect a wide range of vertebrate and invertebrate species, although this chapter is very largely restricted to poxviruses of chordates. Some poxviruses cause severe disease such as smallpox, camelpox, or myxomatosis, but equally poxviruses may cause only asymptomatic infections. Historically, these viruses have played important roles in human medicine and biomedical science. The most serious human poxvirus, variola virus, caused the disease smallpox. This disease was eradicated in 1977 but, remarkably, the origin of the smallpox vaccine (vaccinia virus) remains an enigma of virology. For reviews of poxvirus properties see

Poxvirus replication, as well as Fenner (1996) and Moss (2001).

HISTORICAL ROLES OF POXVIRUSES

Poxviruses have played important roles in human history, medicine, and biological science. Smallpox was a devastating disease that killed up to 40 percent of those infected and has influenced the history of mankind (Hopkins 1983; Fenner et al. 1988; Glynn and Glynn 2004). It is likely that this disease became prevalent after *Homo sapiens* adopted intensive agriculture rather than living as a hunter-gatherer. This profound change in our behavior took place between 5 000 and 10 000 BC and enabled human population densities to increase so that diseases such as smallpox and measles could remain endemic. It has been estimated that populations of at least 300 000 are needed for measles to survive in mankind. In popula-

tions smaller than this, an epidemic would leave too few nonimmune hosts for the virus to be transmitted and so it could not persist in the population. Smallpox is less easily transmitted from person to person than measles, and so the population needed for smallpox to remain endemic was smaller and might be closer to 100 000. It is uncertain exactly when smallpox appeared in man, but examination of the mummified corpse of the Egyptian pharaoh Ramses V, who died in 1160 BC, revealed characteristic dermal pocks, suggesting he may have died from the disease. Smallpox probably existed in man for many centuries previously, although there is no proof of this.

Smallpox was caused by Variola virus, a member of the genus *Orthopoxvirus* (Table 1). When this disease was introduced into hitherto naive populations the effect was devastating. For instance, the introduction of smallpox into Central America in the early sixteenth century decimated the local American Indian population and helped the Spanish invaders to conquer the Aztec nation with 500 soldiers. Smallpox had a profound effect on the population of Europe and it is estimated to have killed between 200 000 and 600 000 people annually during the sixteenth and seventeenth centuries. Even during the twentieth century, smallpox was a major cause of premature mortality. In 1967 there were 131 418 cases of smallpox reported from 44 countries, but due to under-reporting the real number of cases may have been nearer to 10 million (Henderson 1976). For reviews of smallpox in history, the reader is referred to excellent texts on this topic (Hopkins 1983; Fenner et al. 1988; Glynn and Glynn 2004).

THE ERADICATION OF SMALLPOX

The eradication of smallpox has been described in a monumental book *Smallpox and its eradication* (Fenner et al. 1988) and only an outline is given here. Before Edward Jenner introduced vaccination in 1796, the only means of preventing smallpox was variolation (also called inoculation). This involved the deliberate inoculation of infectious variola virus into the skin (usually the upper arm) of the patient brave enough to be infected. The matter inoculated came directly from a patient with smallpox, or was taken from such a patient and stored in dry form until use. Introduction of the virus into the skin gave a less serious disease than that following natural infection via the respiratory tract. Nevertheless, variolation could, and did, cause serious disease and approximately 1 percent of variolated patients developed smallpox and died. Moreover, both these patients and those who survived the infection were able to transmit the infection to others and start epidemics. So variolation was a dangerous practice and was tolerated only because of the tremendous fear of contracting smallpox naturally.

Jenner himself was a variolator and was well aware of the risks and perhaps this contributed to his search for an alternative and safer way to prevent smallpox. Jenner noticed that milkmaids who sometimes became infected on their hands with cowpox virus derived from the cows they milked were spared from smallpox when an epidemic would rage through the community. They were also resistant to variolation. Although Jenner was not the first to notice these facts, he was the first to test systematically the hypothesis that it was the prior

c) Includes variola major and variola minor (alastrim).
d) Includes isolates from felines and captive exotic species.

infection with cowpox virus that caused immunity to smallpox. For this he rightly deserved the accolade for the discovery of vaccination. On 14 May 1796, Jenner vaccinated a boy, James Phipps, with material taken from the hand of a milkmaid, Sarah Nelmes, who had been infected from her cow, Blossom. Subsequently, Jenner demonstrated that Phipps was resistant to variolation. His work was submitted to the Royal Society of London, but not accepted. After being unable to publish his discovery, Jenner performed more vaccinations to obtain additional data in support of his theory. He showed by challenging some of these vaccinees that they too were resistant to variolation (Figure 1). In 1798, he wrote his famous article *An enquiry into the causes and effects of variolae vaccinae, a disease discovered in some of the western countries of England, particularly Gloucestershire, and known by the name of Cowpox* and published this privately (Jenner 1798). The success of vaccination was evident rapidly and enabled Jenner to predict in 1801, that 'the annihilation of the smallpox, the most dreadful scourge of the human species, must be the final result of this practice' (Jenner 1801). This prophecy was correct but took another 176 years to be fulfilled. Jenner's discovery of vaccination was not patented and he did not seek financial reward from it. Perhaps partly in view of this, in 1802 the British Parliament debated his discovery and awarded him a sum of £10 000, a princely sum in the early nineteenth century. In the same year, the American president, Thomas Jefferson, said of vaccination and Jenner, 'Medicine has never before produced any single improvement of such utility. You have erased from the calendar of human afflictions one of its greatest.' Five years later the British Parliament awarded Jenner another £20 000. In view of the success of vaccination and the dangers inherent in variolation, the latter practice was banned in the UK by Act of Parliament in 1840.

Given that vaccination was so effective in preventing smallpox, why did eradication take so long? Factors that contributed to this were the shortage of vaccine, loss of vaccine potency, and the refusal of some people to be vaccinated due to fear of vaccination or prejudice. From Jenner's discovery until the third quarter of the twentieth century, the vaccine supply was inadequate. Cowpox was a relatively rare disease and even though vaccine was also derived from horses, where it caused a disease called 'the grease,' vaccine shortage was a frequent problem. To overcome this, virus was passaged in humans by arm-to-arm transfer, indeed Jenner himself did this in the second series of vaccinations described in the enquiry (Figure 1). This method was used to disseminate the vaccine throughout Europe and the Spanish adopted it to transfer the vaccine to Central America in 1803. Twenty-two orphan children were taken on a voyage across the Atlantic Ocean and groups of children were vaccinated regularly en route so that virus was still growing on one or more children when the ship reached the Americas.

The process of arm-to-arm transfer provided an increased supply of vaccine but was also dangerous because it disseminated other pathogens and both measles and syphilis were transmitted in this way. Consequently, arm-to-arm transfer was banned in the UK by the Vaccination Act of 1898, but not before several epidemics of other diseases had been started. In 1885, in a shipyard in Bremen, Germany, an outbreak of

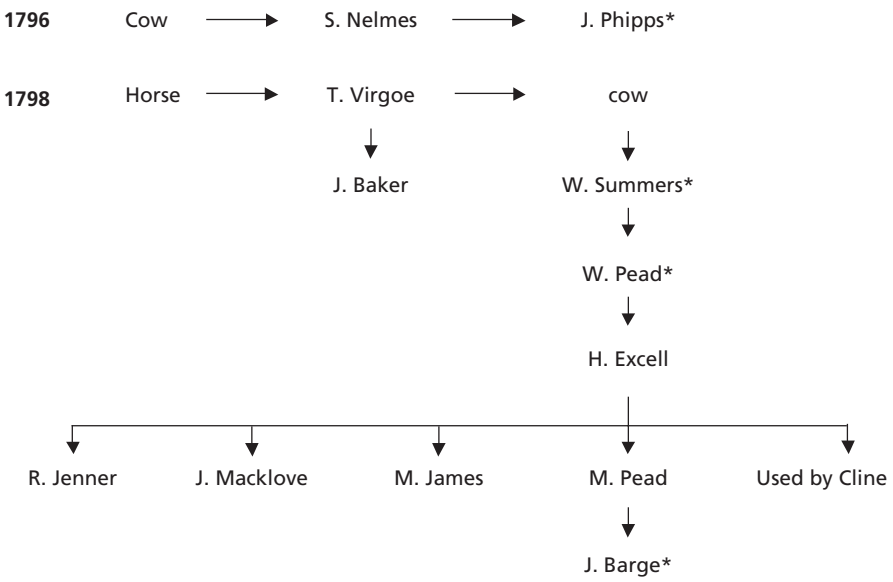

Figure 1 *The series of vaccinations performed by Jenner (1798). Nelmes and Virgoe were infected accidentally from a cow and a horse, respectively. An asterisk indicates that this person was resistant to subsequent variolation (redrawn from Baxby (1981) with permission).*

infectious hepatitis, very likely caused by hepatitis B virus, was blamed on a contaminated batch of smallpox vaccine composed of human lymph. This represented the first documented epidemic of infectious hepatitis B virus (Lurman 1885).

From the 1880s onwards, vaccine was produced on the skin of calves and became known as calf lymph vaccine. This was more plentiful, more easily standardized and free from some other human pathogens. Its proper use led to the containment of smallpox in parts of the world, but in many places the disease remained endemic. This was due partly to inadequate control of vaccine potency and this was a particular problem in tropical regions. In the early 1950s this problem was overcome by Leslie Collier and co-workers at the Lister Institute in London who developed a method to freeze-dry the vaccine such that it was stable at ambient temperature for long periods (Collier 1954, 1955). In fact the vaccine prepared in this way has remarkable stability and can resist incubation at 37°C for 3 months or even 100°C for 1 h. This was a very major advance, for now the vaccine could be used throughout the world and reconstituted under field conditions without loss of potency.

In 1959, the Soviet Union proposed to the World Health Organization that smallpox should be eradicated from the world. This proposal was endorsed enthusiastically, but despite the availability of stable vaccine there was relatively little progress during the next decade and, as mentioned above, smallpox was still endemic in at least 44 countries in 1967. After 1967, the vaccination policy was modified. Hitherto the objective was to vaccinate everyone, but obtaining blanket vaccination was virtually impossible. After 1967, ring vaccination was adopted and was more effective. This relied upon surveillance, quarantine, and vaccination. Photographs of smallpox patients were distributed widely and those identifying a case of smallpox were rewarded financially. Once identified, the patient was quarantined and all contacts were traced and vaccinated. These contacts were observed and if they developed fever, they were quarantined, and their contacts were traced and vaccinated. By this method, the spread of infection was halted and the focus of infection snuffed out. This was highly effective so that by 1975 the last case of smallpox occurred in the Indian subcontinent and the last naturally occurring case of smallpox was recorded in October 1977 near Mogadishu in Somalia.

Sadly, this was not the last case of smallpox and there was an outbreak in Birmingham, UK in 1978 following the escape of variola virus from a laboratory. In this outbreak one person died. Notably this fatality occurred despite the patient having been vaccinated twice previously, once as a child and once 12 years before contracting the disease. So immunity is not lifelong and this was recognized by the World Health Organization who recommended that those working in areas where smallpox was endemic should be vaccinated every 3 years. Of all the claims made by Jenner in 1798 about vaccination, nearly everything was correct except his belief that vaccination provided lifelong immunity.

It is largely because of the tragedy in Birmingham in 1978 that today the stocks of variola virus are held in only two locations in the world, in the Centers for Disease Control and Prevention, Atlanta, USA and in Vector, Novosobirsk, Russia. These stocks are stored in maximum security (BSL4) laboratories and all work with live virus requires prior approval by the World Health Organization which also inspects these laboratories regularly. The chance of an escape of virus from these sites is at best remote, but the concern about the potential use of variola virus in bioterrorism (see below) derives not so much from these virus repositories but from the possibility that the virus is held elsewhere illegally.

THE ORIGIN OF VACCINIA VIRUS

The virus used by Jenner in 1796 as the first human vaccine may have been cowpox virus, although this is uncertain because the original virus is not available for characterization. We know only that the virus was taken from the hand of Sarah Nelmes, who presumably was infected from her cow, and this virus was used to immunize James Phipps (Jenner 1798). However, vaccine was not only acquired from cows. In the series of vaccinations in 1798, described in Jenner's Enquiry, it is stated that Thomas Virgoe was infected from a horse and from Virgoe the virus was used to vaccinate a 5-year-old boy, John Baker (Figure 1). In addition, in 1813 and 1817, Jenner sent vaccine derived from horses to the National Vaccine Establishment, which was set up in England to provide smallpox vaccine. Vaccines were therefore derived from both cows and horses.

In 1939 in Liverpool, UK, Alan W. Downie showed that all the vaccines used to prevent smallpox in the twentieth century formed a homogeneous group that was distinct from both cowpox virus and variola virus and represented a distinct species of Orthopoxvirus that became known as vaccinia virus (Downie 1939a, b). If Jenner had used cowpox virus in 1796, sometime between then and 1939 this was replaced by vaccinia virus. Exactly when this took place is uncertain, but it is likely to have been early during the nineteenth century. Several anecdotes support his conclusion. First, the smallpox vaccine that was taken to the USA in 1856, was passed serially thereafter and became the New York City Board of Health vaccine, is vaccinia virus and not cowpox virus. Second, pathologists from the late nineteenth century who studied the cytopathic effect induced by the smallpox vaccine, noted the eosinophilic B type inclusion bodies that are made by both vaccinia virus and cowpox virus, but did not report the more obvious A type inclusion bodies that are made by cowpox virus and not vaccinia virus. Lastly, the drawings made of lesions induced by the vaccine used by Jenner are

similar to those induced by the vaccine in use today. So it is possible that Jenner used vaccinia virus, or cowpox virus, or both, but at different times. Both these viruses have a broad host range and may infect many species.

This origin of vaccinia virus was reviewed by Baxby (1981) and he suggested that it might be horsepox virus. If so, perhaps our language is wrong; for the name of the smallpox vaccine should be equinia virus (not vaccinia virus), and we use equines (not vaccines) to equinate people by the process of equination! It is remarkable that vaccinia virus is the only vaccine to have eradicated a human disease and yet its origin and natural host remain an enigma. It is also remarkable, in comparison with the regulatory paperwork needed today before any clinical trial may be undertaken, that for smallpox:

- there was no ethical or safety evaluation given to the first use of the vaccine, or the challenge of vaccinated subjects;
- the paper reporting the use of the vaccine to prevent smallpox did not survive peer-review;
- there was no properly controlled clinical trial to demonstrate the efficacy of the vaccine;
- there was (and is) no understanding of how the vaccine worked.

Yet there was anecdotal evidence that the vaccine worked: namely the global eradication of smallpox.

OTHER CONTRIBUTIONS OF VACCINIA VIRUS TO BIOMEDICAL SCIENCE

Despite its uncertain origin, vaccinia virus has played several seminal roles in biological science and medicine. In addition to its use to eradicate smallpox, vaccinia virus was the first mammalian virus to be purified, analyzed chemically, and titrated accurately. Work with vaccinia virus in the 1960s discovered the first virus-encoded nucleic acid polymerase (Munyon et al. 1967) and this discovery prompted the search for polymerases in other viruses. The study of vaccinia virus enzymes that catalyze the addition of a methylated cap structure at the 5′ end (Martin and Moss 1975) and a poly(A) tail at the 3′ end of mRNAs (Brown et al. 1973) have been informative for the study of these cellular processes. In 1982, genetically engineered vaccinia viruses were constructed that expressed genes derived from other organisms (Mackett et al. 1982; Panicali and Paoletti 1982) and such recombinant viruses were shown to have potential as vaccines against other infectious agents (Panicali et al. 1983; Smith et al. 1983a,b). This concept pioneered the development of genetically engineered viruses as live vaccines, a concept applied subsequently to other viruses and micro-organisms. More recently, studies of poxvirus virulence have revealed a wide range of proteins that inhibit specific components of the host immune response to infection (Seet et al. 2003). Lastly, studies of the interaction of vaccinia virus with the host cell have discovered how these viruses exploit cell biology to enable their entry into, movement within, and exit from the cell (Smith et al. 2003). Although smallpox has been eradicated and poxviruses now cause little human disease, there are compelling reasons to continue to study these viruses.

CLASSIFICATION

The *Poxviridae* is divided into the *Entomopoxvirinae* and *Chordopoxvirinae* subfamilies that infect insects and chordates, respectively (Table 1). The entomopoxviruses are subdivided into three genera (*A*, *B*, and *C*), although genome sequence data from two members of group B (Melanoplus sanguinipes and Amsacta moorei) have revealed considerable diversity suggesting that these viruses might be reclassified in different genera (Afonso et al. 1999; Bawden et al. 2000). The genomes of these entomopoxviruses are rich in adenine and thymine (A+T), 81.5 and 81.7 percent. These viruses are not considered further here and the reader is referred to other reviews of this topic (Moyer 1994, 1999).

The chordopoxviruses are now considered in greater detail. This subfamily is divided into eight genera: *Orthopoxvirus*, *Leporipoxvirus*, *Molluscipoxvirus*, *Avipoxvirus*, *Yatapoxvirus*, *Suipoxvirus*, *Capripoxvirus*, and *Parapoxvirus* (see Table 1). Within each genus there are distinct species and often there are multiple strains of each species. For instance, the genus *Orthopoxvirus* contains several members, one of which is *Vaccinia virus* and there are a score or so different *Vaccinia virus* strains. Historically, the definition of a genus is that its members are immunologically cross-reactive and cross-protective, whereas viruses of different genera are neither cross-reactive nor cross-protective. This has been a reasonable method of classification and is largely supported by the analysis of virus genome sequences that are becoming available.

Sequencing of additional poxviruses from divergent species may cause an increase in the number of genera. For instance, poxviruses have been isolated from north American deer (Afonso et al. 2002), Finnish reindeer (Tikkanen et al. 2004), farmed Nile crocodiles (Horner 1988), Mongolian horses (Tulman et al. 2002a), South African sea lions (Wilson and Poglayen-Newall 1971), lizards (Stauber and Gogolewski 1990), kangaroos (Bagnall and Wilson 1974), squirrels (Thomas et al. 2003), South American rodents (Ueda et al. 1978; Esposito et al. 1980), and chameleons (Jacobson and Telford 1990). In addition, orthopoxviruses that resemble vaccinia virus strains were isolated from buffaloes in India (Dumbell and Richardson 1993), and cattle (de Souza Trindade et al. 2003) and rodents (Fonseca et al. 1998; da Fonseca et al., 2002) in South America. Possibly these viruses became endemic after transmission from man following widespread use of vaccinia virus as the smallpox vaccine.

IDENTIFICATION OF POXVIRUSES

Traditionally, the identification of poxviruses has been based upon biological observations, such as species of origin, growth properties in animal tissue or on the chorioallantoic membrane of the fertile hen's egg, reactivity with specific sera, and electron microscopy. These observations remain useful, but the rapid identification of a new virus as a poxvirus is now usually done by electron microscopy, polymerase chain reaction (PCR) (Meyer et al. 1994; Ropp et al. 1995; Heine et al. 1999), and genome sequencing. PCR shows great sensitivity, speed, and specificity. For instance, using specific sets of oligonucleotide primers it is possible to say not only that a new isolate is an orthopoxvirus, but which species it is. This was useful for the identification of the agent causing fever and generalized rash in humans in the midwest of USA during 2003 as monkeypox virus (Reed et al. 2004). PCR-based detection methods have been developed, validated, and deployed to detect variola virus that might be deliberately released by bioterrorists (see below) (Sofi Ibrahim et al. 2003).

PHYLOGENETIC RELATIONSHIPS

Genomes of representative members of all *Chordopoxvirus* genera have been sequenced (see http://www.poxvirus.org for details) and all except the parapoxviruses (that were sequenced most recently) have been used in phylogenetic comparisons (McLysaght et al. 2003; Upton et al. 2003; Gubser et al. 2004). These genomes range in size from 135 kb (Yaba monkey tumor virus) (Brunetti et al. 2003) to 288 kb (a pathogenic strain of fowlpox virus from the Animal Health Inspection Service Center for Veterinary Biologics, Ames, IA, USA) (Afonso et al. 2000) and from 36 percent A+T in genus *Parapoxvirus* to 75 percent A+T in capripoxvirus. All these genomes share a similar overall arrangement. In the central region (approximately 100 kb) the genes are conserved and many of these encode proteins that are essential for virus transcription, DNA replication, or assembly of new virions (Figure 2). In this region there are 90 genes that are conserved in all sequenced chordopoxviruses, but this number decreases to 49 when the entomopoxviruses are included, reflecting the greater diversity of the latter group. Genes in the terminal regions of the chordopoxvirus genomes are more variable and most are nonessential for virus replication in cell culture. Indeed, outside the central conserved region there is no gene that is conserved in all sequenced chordopoxviruses. These nonessential genes encode luxury functions that aid the virus in vivo and may function to inhibit aspects of the host immune response to infection, or influence host range and virulence (Smith and McFadden 2002). The types of genes that are present here reflect the different life styles that these viruses have evolved with their hosts.

A phylogenetic comparison of the chordopoxviruses (excluding parapoxviruses) using 17 of the 49 genes that are conserved in all poxviruses revealed that the sequenced *Chordopoxvirus* genera fall into four groups (Gubser et al. 2004) (Figure 3). An analysis using a different collection of genes reached a very similar conclusion (McLysaght et al. 2003). The most divergent group is the *Avipoxvirus* genus represented by *Fowlpox virus* (FPV). This avian virus has the largest genome (288 kb), the greatest number of genes that are unique to any genus (113), and the most divergent genome organization. Whereas genomes of all the other *Chordopoxvirus* genera have a consistent order and orientation of genes within the conserved, central region, FPV differs in that there are genome inversions and translocations (Figure 2).

The next most divergent group is the genus *Molluscipox virus*. This contains a single member, *Molluscum contagiosum virus*, of which there are two types, that infects only man. This virus also has many (70) unique genes that are not found in other *Chordopoxvirus* genera. It also lacks many genes found in other poxviruses such as those involved in immune regulation and instead has its own unique set of immunoregulators (Senkevich et al. 1996, 1997).

The third group includes the genera *Leporipoxvirus*, *Suipoxvirus*, *Yatapoxvirus*, and *Capripoxvirus*. These genomes are all smaller than those of the *Orthopoxvirus* genus and have several common features. For instance, the counterpart of *Vaccinia virus* strain Copenhagen gene *C7L* is present in these genera in the central region of the genome rather than being near the left end in members of the genus *Orthopoxvirus* (Figure 2).

The last group is represented by genus *Orthopoxvirus*. Orthopoxviruses have genomes of approximately 200 kb that are rich in adenine and thymine (67 percent) and form a tight cluster. They are distinguished from other chordopoxviruses by the presence of genes corresponding to *Vaccinia virus* strain Copenhagen genes *F14L*, *E7L*, and *O2L* within the central conserved region. Orthopoxviruses have been of greatest importance to man and most members of this genus have been sequenced. In addition to *Variola virus*, this genus includes *Vaccinia virus*, *Cowpox virus*, *Ectromelia virus*, the cause of mousepox, *Monkeypox virus*, and *Camelpox virus* (Table 1). Some of the names of these species are misnomers; for instance, neither *Cowpox virus* nor *Monkeypox virus* are naturally resident in cows or monkeys, instead they have rodent or squirrel reservoirs and may be transmitted to cows, monkeys, man, and other species as zoonoses (Khodakevich et al. 1987a; Crouch et al. 1995; Kulesh et al. 2004).

Although the parapoxviruses were not included in the above analysis, the genomes of orf virus and *Bovine papular stomatitis virus* were sequenced recently (Delhon

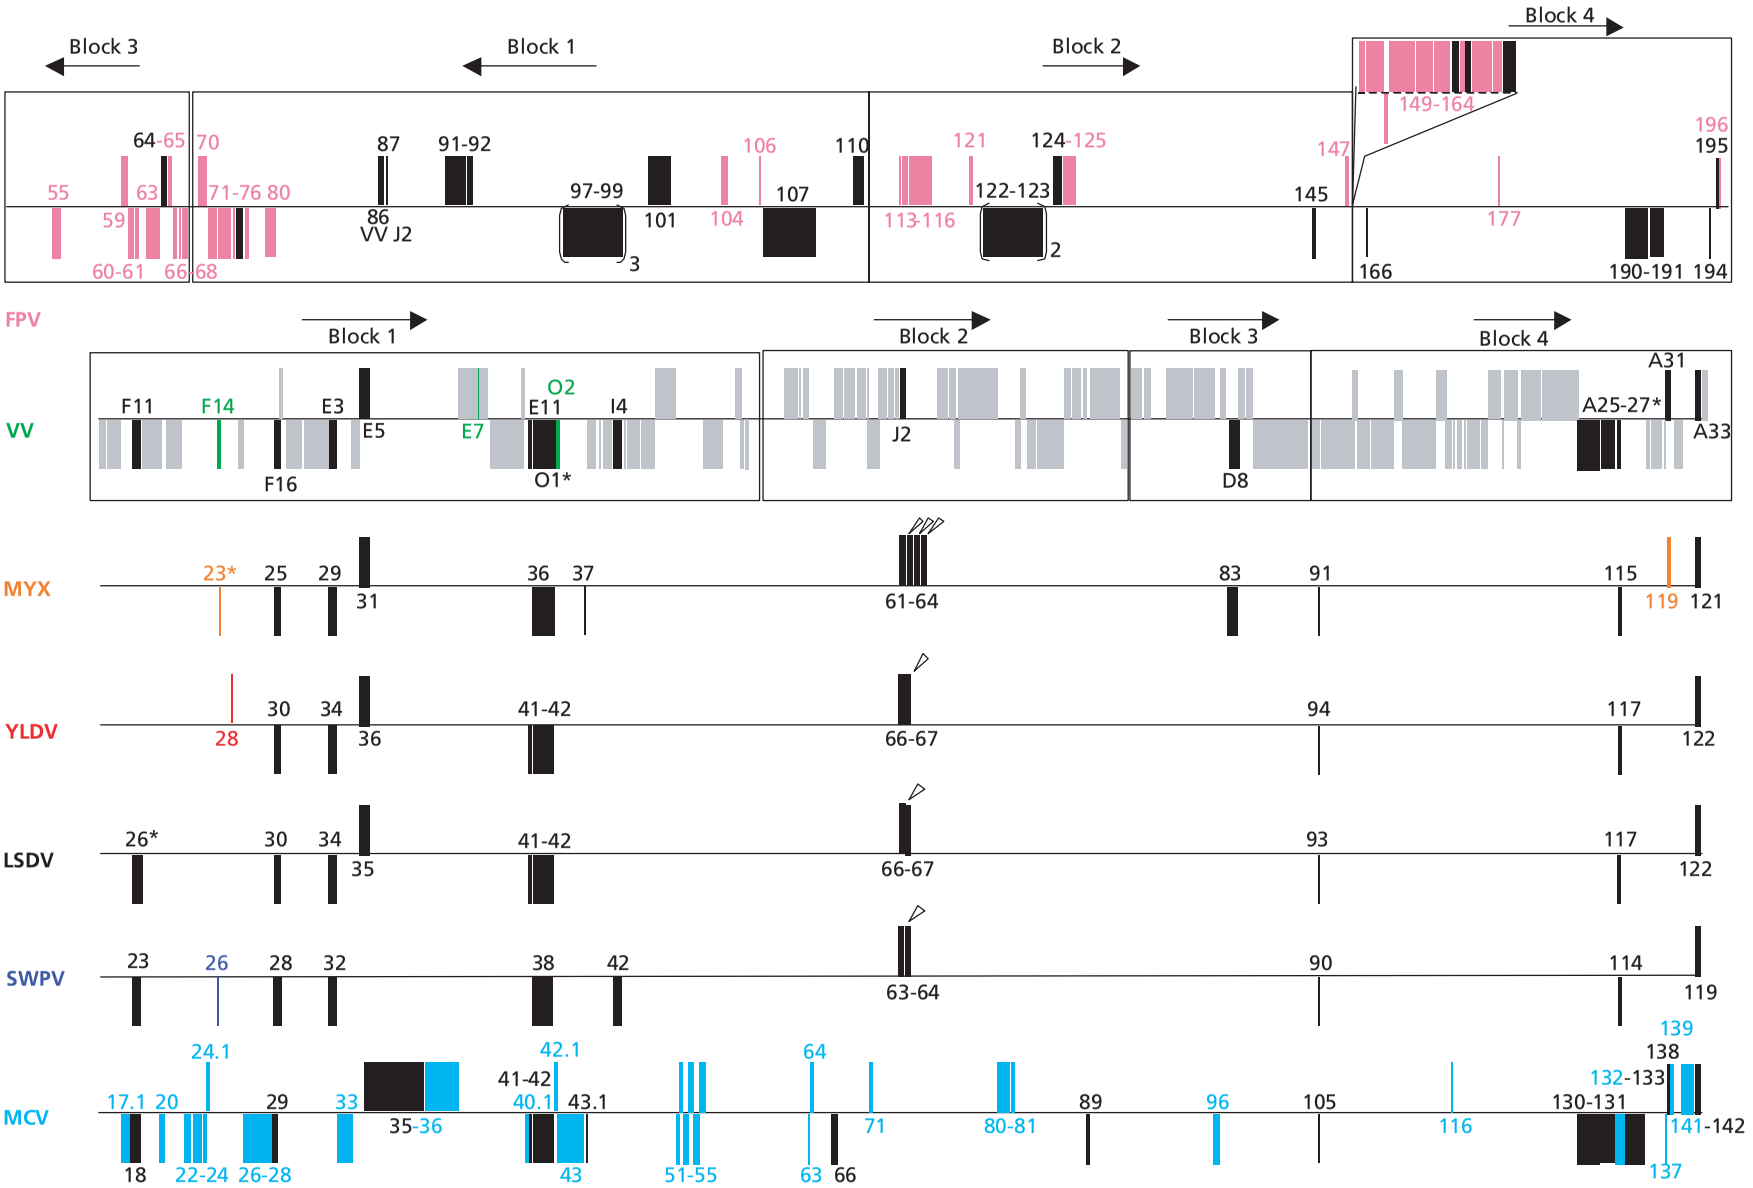

Figure 2 *Comparison of the gene content of the central region of the prototype virus from different Chordopoxvirus genera. vaccinia virus strain Copenhagen (VV) is the reference against which the other viruses (FPV, fowlpox virus; MYX, myxoma virus; YLDV, Yaba-like disease virus; LSDV, lumpy skin disease virus; SWPV, swinepox virus; MCV, Molluscum contagiosum disease virus) are compared. For each virus, genes (vertical bars) that are transcribed rightwards or leftwards are shown above or below the horizontal line, respectively. The 90 genes that are conserved in all sequenced chordopoxviruses are shown in gray for vaccinia virus. Genes conserved between two or more viruses from the different genera (but not one of the 90 conserved genes) are shown in black and genes that are unique to one genus are represented in the same color as the virus name. Genes that are present in only some members of a specific genus, but are fragmented or absent in other members of that genus, are indicated with an asterix. Block 1, counterparts of vaccinia virus strain Copenhagen F9L-G4L; block 2, counterparts of vaccinia virus strain Copenhagen G5R-D2L; block 3, counterparts of vaccinia virus strain Copenhagen D3R-A1L; block 4, counterparts of vaccinia virus strain Copenhagen A2L-A34R. The arrows illustrate the orientation of the blocks within the vaccinia virus and fowlpox virus (FPV) genomes. Arrowheads indicate the positions of orthologs of VV-COP gene C7L (Redrawn from Gubser et al. (2004) with permission).*

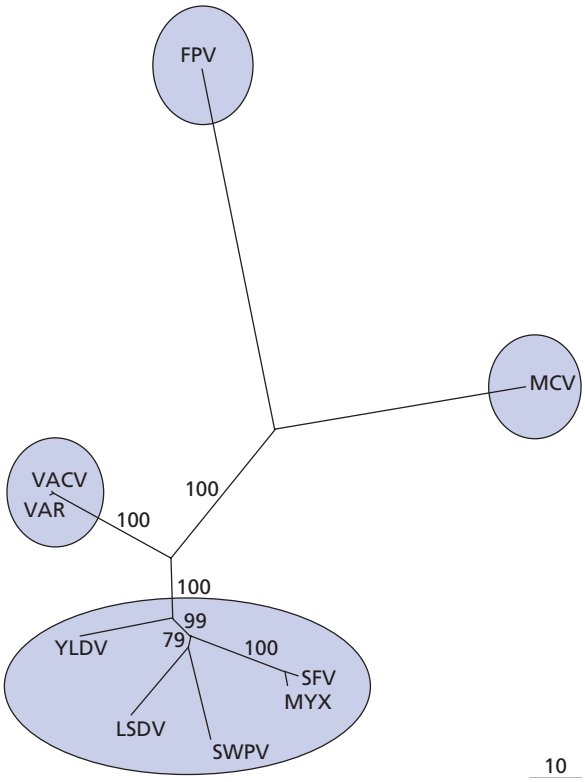

Figure 3 *Phyogenetic comparisons of chordopoxviruses. The amino acid sequence of 17 poxvirus proteins (corresponding to vaccinia virus strain Copenhagen E9L, I7L, I8R, G9R, J3R, J6R, H2R, H4L, H6R, D1R, D5R, D6R, D11L, D13L, A7L, A16L, and A24R) were aligned and an unrooted maximum-likelihood tree was obtained using the program ProML from the Phylip package version 3.0. The bootstrap values from 1 000 replica samplings and the divergence scale (substitutions/site) are indicated. Abbreviations as in Figure 2. Redrawn with modifications from Gubser et al.(2004) with permission.*

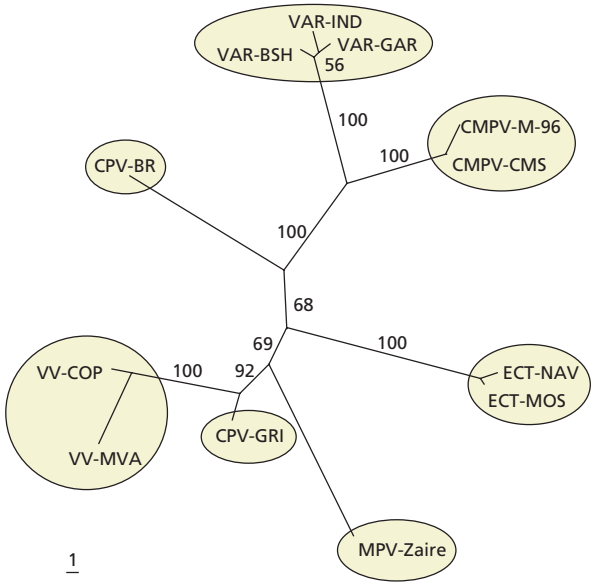

Figure 4 *Unrooted maximum likelihood phylogenetic tree showing the relationships of 12 orthopoxviruses. The amino acid sequences of proteins corresponding to vaccinia virus strain Copenhagen C6L, C7L, N1L, K2L, F2L, F4L, F6L, F8L, A56R, B1R, B5R, B15R (all encoded in the terminal regions of the genomes) were aligned and used to generate the tree using the program ProML. The bootstrap values from 1 000 replica samplings and the divergence scale (substitutions/site) are indicated. VAR-IND, variola virus strain India 1967; VAR-BSH, variola virus strain Bangladesh 1975; VAR-GAR, variola virus strain Garcia 1966; CPV-BR, cowpox virus Brighton Red; CPV-GRI, cowpox virus GRI-90; CMPV-CMS, camelpox virus strain CMS; CMPV-M-96; camelpox virus M-96; ECT-Nav, Ectromelia virus strain Naval; ECT-MOS, Ectromelia virus strain Moscow; VV-COP vaccinia virus strain Copenhagen; VV-MVA, vaccinia virus strain modified virus Ankara; MPV-Zaire, monkeypox virus strain Zaire. Redrawn with modifications from Gubser et al. (2004) with permission.*

et al. 2004), and phylogenetic trees including these viruses or sequences from other parapoxviruses (Tikkanen et al. 2004) showed that parapoxviruses are quite separate from other *Chordopoxvirus* genera, and the nearest genus is *Molluscipoxvirus*. The parapoxviruses share with molluscipoxviruses a high GC content and lack several genes encoding enzymes for nucleotide metabolism that are found in other chordopoxviruses.

A phylogenetic comparison of the orthopoxviruses using 12 genes that are conserved in the terminal regions of these genomes (Figure 4) showed that *Variola virus* and *Camelpox virus* are closely related (Gubser and Smith 2002), but *Monkeypox virus* is one of the most divergent viruses of this genus despite causing a disease in man similar to smallpox (Gubser et al. 2004). Another study using a different collection of genes conserved in these viruses came to a similar conclusion (McLysaght et al. 2003). These observations imply that one or more of these viruses have jumped species during their evolution; for *Variola virus*, a human virus, is closer to a virus that infects only camels than to *Monkeypox virus* that infects man, primates, and other species. Different strains of most *Orthopoxvirus* species form a tight cluster, consistent with their classification, however, with *Cowpox virus* the two sequenced members, Brighton Red (BR) and GRI-90 (Shchelkunov et al. 1998), are sufficiently divergent to justify their reclassification as separate species (Gubser et al. 2004). It will be interesting to compare the sequences of *Vaccinia virus* and *Cowpox virus* strains with the geographical site of isolation. Another interesting conclusion from the phylogenetic study of McLysaght et al. (2003) was that the rate of gene acquisition by the orthopoxviruses has been greater than that for *Leporipoxvirus*, *Suipoxvirus*, *Capripoxvirus*, and *Yatapoxvirus*.

There has also been significant gene loss during the evolution of the orthopoxviruses from the immediate ancestor of this group. This was shown by several genes being disrupted by mutation in one of more virus, but intact in at least one other (Aguado et al. 1992; Gubser and Smith 2002). An example is a gene encoding a soluble binding protein for interleukin (IL)-1β in many strains of *Vaccinia virus* and *Cowpox virus* (Alcami and

Smith 1992, 1996; Spriggs et al. 1992), but the disruption of this gene in all sequenced strains of variola virus. Similarly, a gene in *Vaccinia virus* that encodes an enzyme that synthesizes steroid hormones (Moore and Smith 1992) is disrupted in *Variola virus* strains into small fragments (Aguado et al. 1992; Shchelkunov et al. 1995).

There has also been recombination between *Orthopoxvirus* genomes during the evolution of these viruses. Evidence for this came from comparing the sequences of genes from the terminal regions of *Cowpox virus* strain BR and *Ectromelia virus* strain Naval with the corresponding genes from (1) the *Variola virus*/*Camelpox virus* subgroup; and (2) the *Vaccinia virus* subgroup (Gubser et al. 2004). This revealed that genes from the left end of *Cowpox virus* BR were closer to the *Vaccinia virus* subgroup than to the *Variola virus*/*Camelpox virus* subgroup. However, genes from the right end of *Cowpox virus* BR had the opposite relationship. Conversely, genes taken from the right end of *Ectromelia virus* Naval were closer to the *Vaccinia virus* subgroup, whereas genes from the left end were roughly equidistant from either group (Gubser et al. 2004).

VIRION STRUCTURE

This topic has been the subject of much debate and disagreement and is considered in detail in
Poxvirus replication. It is mentioned briefly here because the conclusion of this author differs from that of Moyer and Condit. Using vaccinia virus as the model poxvirus, there is general agreement that there are two forms of infectious virus produced from each infected cell, the intracellular mature virus (IMV) and extracellular enveloped virus (EEV), for review see Smith et al. (2002). There is also agreement that EEV contains one more membrane than IMV, but the number of membranes around IMV, how this (these) are formed and how each form of virus enters cells have been disputed. Originally, IMV was proposed to be surrounded by a single membrane that was synthesized de novo (Dales and Siminovitch 1961). Later, this model was challenged by workers who claimed there were two closed apposed membranes derived from the intermediate compartment of the cell, although it was acknowledged by these authors that 'the membranes of this cisterna are so tightly apposed that it is often difficult to distinguish the two bilayers' (Sodeik et al. 1993). Subsequently, measurement of the thickness of the IMV membrane structure found only a single lipid bilayer of 5 nm (equivalent to the thickness of cell membranes) and no continuity was detected with cell membranes (Hollinshead et al. 1999). Moreover, clear images were presented showing continuity between a single IMV membrane and the plasma membrane during IMV entry and no other membranes were visible (Armstrong et al. 1973; Chang and Metz 1976). Taken together, these data are interpreted by this author as unequivocal evidence that IMV has only a single membrane and therefore EEV has two. The challenge for the future is to elucidate how a single membrane is formed in the cytoplasm.

DISEASES CAUSED BY POXVIRUSES

Smallpox

Smallpox was a disease of man only and was a life-threatening systemic infection that spread through the body in several phases. Its impact on human health and its influence on our history can hardly be overstated. Even today, 25 years after the eradication of this disease, it has an impact as a potential bioterror weapon and has forced responses from governments around the world (see below).

Infection by variola virus was initiated by inhalation of virions released from the respiratory tract of infected patients or from scab material that had been ground into dust. A detailed study of the spread of virus from the respiratory system to other organs has been impossible in man for obvious reasons, but the mechanism of spread is believed to be similar to that of Ectromelia virus in mice, which causes the systemic disease mousepox (Buller and Palumbo 1991; Fenner 1992). With Ectromelia virus, infection spreads from the epithelium to the local lymph nodes where the virus replicates and is released into the blood stream (primary viremia) as free virions or within infected white cells. From here the virus causes an extensive infection of the reticuloendothelial system and higher levels of virus are released into the bloodstream (secondary viremia). Finally, the virus reaches the dermis where it induces formation of the characteristic skin lesions. With smallpox, there was a long incubation period before the patient became ill (8–14 days, average 11). Illness started with malaise, fever, aches, and prostration. The skin lesions progressed from papules to macules to blisters with a clear fluid containing virus. Eventually the lesions dried forming scabs that detached leaving a local scar. Once all scabs had detached from the body, the patient was no longer infectious. Smallpox lesions had a characteristic centrifugal distribution that was helpful in its diagnosis and distinction from chickenpox caused by a herpes virus, varicella-zoster virus. Smallpox lesions were abundant on the face, hands, and feet and less so on the trunk. In contrast, lesions caused by chickenpox are more abundant on the trunk than the periphery.

The mortality resulting from infection by variola virus depended upon whether infection was caused by variola major or variola minor and whether there was existing immunity. Infection by variola major in unvaccinated patients or immunologically naive populations caused up to 40 percent mortality, whereas with variola minor (also called alastrim) mortality was approximately 1 percent

(Fenner et al. 1988). Factors that predisposed to greater disease severity were immunological deficiency and pregnancy. The degree of protection provided by existing immunity depended on the time since vaccination, for epidemiological evidence showed that immunological protection does not endure for life. Those immunized long ago do have residual humoral or cell-mediated immunity or both (Hammarlund et al. 2003; Terajima et al. 2003), but it is uncertain if this will prevent infection or disease. Existing immunity may protect against mortality in most cases, but those infected might still transmit virus to others. Despite the sequencing of the genomes of minor and major strains of variola virus, it has not been possible to elucidate the basis for this large difference in virulence (Shchelkunov et al. 2000).

Monkeypox

This disease is caused by monkeypox virus, so called because it was isolated first from captive monkeys in Copenhagen in 1958, but its natural host is probably rodents and or squirrels in central and west Africa (Khodakevich et al. 1987a, b; Jezek and Fenner 1988; Kulesh et al. 2004). Monkeypox virus causes a disease in man that is clinically similar to smallpox and, until 2003, outbreaks were associated with significant mortality (1–10 percent). One important difference between monkeypox and smallpox is that the former is transmitted less efficiently from human to human and so outbreaks of monkeypox in man have tended to be isolated index cases or with very short chains of human transmission. The recognition of monkeypox as a human disease during the latter stages of the smallpox eradication campaign was of concern to the World Health Organization because it was feared that this virus might mutate into a variola-like virus and cause increased human-to-human transmission. Worse, if this virus retained its broad host range and became endemic in nonhuman hosts, it might be introduced repeatedly into man from an animal reservoir. However, these fears were largely dispelled by the sequencing of the monkeypox virus genome that showed that, within the *Orthopoxvirus* genus, monkeypox virus is one of the more divergent viruses from variola virus (Shchelkunov et al. 2001) and so evolution into a variola-like virus seems unlikely by passage and mutation.

In 2003, there was an outbreak of monkeypox in the USA that was caused by the importation of Gambian rodents (Di Giulio and Eckburg 2004; Reed et al. 2004). These rodents carried monkeypox virus without overt signs of illness, but transmitted the virus to American rodents, including prairie dogs, when cohoused in pet shops. The infected prairie dogs became ill and, as household pets, transmitted infection to man by close bodily contact, skin abrasions, or bites. Of the 81 humans infected, many became seriously ill, but there were no fatalities. Human infection was attributed to contact with infected animals rather than human-to-human transmission.

The epidemic outbreak of a febrile illness associated with a pustular rash caused concerns in USA that smallpox had re-emerged, and this fear was increased when the cause of the disease was diagnosed by electron microscopy as a poxvirus. However, these fears were allayed promptly when monkeypox virus was identified by PCR. Genome sequencing showed that the isolates from man and prairie dogs were very closely linked and were distinct from the strain of monkeypox virus that was sequenced from central Africa (Zaire) (Shchelkunov et al. 2001). This difference may explain the lack of mortality during the USA epidemic, compared with outbreaks in central Africa where mortality was up to 10 percent. Alternatively, the infected populations might have different inherent susceptibility to the disease or the disease outcome was affected by different quality of health care.

The episode of monkeypox in USA in 2003 has caused legislation banning the importation of exotic animals to be enacted and importation must now be subject to careful screening and quarantine.

Cowpox virus

Cowpox virus, like monkeypox virus, is a misnomer as the virus is not naturally resident in cows and its reservoir is probably rodents (Baxby et al. 1994; Crouch et al. 1995; Chantrey et al. 1999). However, cowpox virus has a broad host range and has infected many animals including rodents, large felines, domestic cats, cows, man, and elephants. In man, cowpox virus infections are usually single lesions (sometimes with satellites) on the hands that were acquired by handling infected animals. These can be painful and take weeks to resolve fully, but usually heal without lasting adverse effects, except for a local scar. The sequences of two cowpox virus strains (Brighton Red and GRI-90) showed that these viruses are quite diverse (see above) (Gubser et al. 2004); however, among the orthopoxviruses, the cowpox virus genomes have the greatest number of intact genes and the fewest number of broken genes fragments. This led to the suggestion that cowpox virus was closest to the ancestral poxvirus from which the other orthopoxviruses evolved (Shchelkunov et al. 1998).

Molluscum contagiosum virus

Molluscum contagiosum virus (MCV) is a strictly human virus that causes benign skin proliferations (often in children) that may persist for a year or more but then resolve. In patients with immunodeficiency caused, for instance, by infection with human immunodeficiency virus (HIV), MCV infections are more severe and a

greater problem. MCV cannot be cultivated in cell culture and its genome has diverged significantly from other chordopoxviruses (Senkevich et al. 1996). Seventy out of the 182 MCV genes are not found in other poxviruses, and some of these encode immunomodulatory proteins unique to MCV (Senkevich et al. 1997). A notable feature of MCV lesions is the walling off of the lesion from the underlying tissue and the restricted infiltration of inflammatory cells into the lesion itself. This is likely to be due to one or more of the immunomodulatory proteins encoded by MCV. The center of the MCV lesion is often packed with new virions that are shed from the lesion surface into the environment. Transmission is by close contact with virus shed form the skin surface.

Parapoxvirus

The genus *Parapoxvirus* includes viruses that infect sheep, goats, and deer (Table 1) and two members of this genus have been sequenced (Delhon et al. 2004). The disease caused by Orf virus has been called contagious pustular dermatitis or scabby mouth and causes significant economic loss in sheep due to the painful lesions on lips and teats that discourage feeding. Virus is shed into the environment and can be transmitted to new stock from infected pasture, or by direct animal to animal contact. A notable feature of orf infections is that animals can be reinfected indicating that prior infection does not induce solid immunity. For a review of *Parapoxvirus* biology, see Robinson and Lyttle (1992). Orf virus lesions have a peculiar pathology and lesions are highly vascularized and this may be due in part to expression of a virus-encoded vascular endothelial growth factor (Lyttle et al. 1994). The gene encoding this protein is nonessential for growth in cell culture but influences the outcome of infection in vivo (Savory et al. 2000). Orf infection can be transmitted to man where it causes dermal skin lesions that can be painful.

Other parapoxviruses include pseudocowpox virus, viruses that infect seals, and a virus of reindeer (Tikkanen et al. 2004). Historically, confusion between cowpox virus and pseudocowpox virus caused Jenner's claim about the efficacy of vaccination against smallpox to be challenged. The use of pseudocowpox virus, which was also obtained from the teats of cows, provided no protection against smallpox because the virus belongs to a different genus, and this caused some to state that Jenner was incorrect.

In cases where the genomes of members of this genus have been analyzed, the genomes are rich in guanosine and cytosine (G+C) (64 percent for Orf virus), but despite this, these viruses have a gene content and genome organization that is conserved with other chordopoxviruses. Overall, they are closest to the genus *Molluscipoxvirus*, and share some features with MCV, such as a G+C-rich genome and few genes for nucleotide metabolism (Delhon et al. 2004).

Leporipoxvirus

The leporipoxviruses infect rabbits. myxoma virus was isolated from its natural host in South America (*Sylvilagus* spp.) in which it does not cause severe disease, but in the European rabbit (*Oryctolagus cuniculus*) it causes the disease myxomatosis (McFadden 1988). Myxoma virus was used in the 1950s to control the huge population of European rabbits that had built up in Australia and its release and adaptation to its host provides an excellent example of how virus and host co-evolve (Fenner and Ratcliffe 1965). Initially, after the release of virulent virus most of the rabbits died and only virulent virus was isolated from the field. Subsequently, the virus strains present in the rabbit population were of more modest virulence, and the surviving rabbits became more resistant to the original virus. This demonstrates that evolution favors the emergence of pathogens of modest virulence. The basis for the changes in virulence of the myxoma viruses isolated from Australia is not understood.

The genome sequences of myxoma virus (Cameron et al. 1999) and Shope fibroma virus (Willer et al. 1999) showed more diversity exists between these leporipoxviruses than between members of genus *Orthopoxvirus*. But like the orthopoxviruses, the terminal regions of the leporipoxvirus genomes encode a diverse range of immunomodulatory proteins that inhibit aspects of the immune response to infection and that have been subject to genetic manipulation and functional characterization (Nash et al. 1999). The virulence of myxoma virus has been assessed largely in the European rabbit where it causes a fatal disease rather than in its natural host where the asymptomatic nature of the infection makes study of pathogenesis more difficult.

Capripoxvirus

The capripoxviruses infect sheep, goats, and cattle in parts of Africa and Asia and are a cause of significant mortality, morbidity, and economic loss. Transmission of infection can be via direct contact and entry through skin abrasions, close airborne transmission, or via arthropod vectors. Comparisons of the genomes (Gershon and Black 1988) and antigenicity (Kitching et al. 1986) of these viruses indicated that they are closely related; nonetheless, these viruses vary considerably in virulence and attenuated strains have been used as live vaccines. The genomes of lumpy skin disease virus and several sheeppox and goatpox viruses have been sequenced and compared (Tulman et al. 2001, 2002b). These studies identified some differences between virulent and attenuated strains near the genome termini, but which changes are responsible for attenuation is unknown. Like other chordopoxviruses, these viruses contain many genes encoding immunomodulators near the genome termini and several of these are unique to the genus *Capripoxvirus*.

Avipoxvirus

The genus *Avipoxvirus* includes a wide range of viruses that are distributed worldwide. Some of these viruses may cause severe disease and are a cause of economic loss in the poultry industry. Respiratory infection is usually more severe than dermal infection. The sequence of the prototype avipoxvirus, fowlpox virus, shows that genus *Avipoxvirus* is the most divergent genus of the *Chordopoxvirus* genera and has the largest genome and the greatest number of genes unique to this genus (see above). A notable feature of some strains of fowlpox virus was the presence of the provirus genome of an avian retrovirus, reticuloendotheliosis virus, integrated into the avipoxvirus genome (Hertig et al. 1997). Although there was no evidence of reverse transcriptase activity in fowlpox virus-infected cells, the integrated retrovirus is infectious because transfection of isolated virus DNA into uninfected cells yielded infectious retrovirus. Comparison of the genome sequences of a virulent (Afonso et al. 2000) and attenuated fowlpox virus genomes (Laidlaw and Skinner 2004) have identified many changes and the basis for attenuation is likely to be multifactorial.

Yatapoxvirus

The genus *Yatapoxirus* (Table 1) contains three members, tanapox virus, yaba monkey tumor virus (YMTV), and yaba-like disease virus (YLDV) and the genomes of the latter two viruses have been sequenced (Lee et al. 2001; Brunetti et al. 2003). *Tanapox virus* was first isolated in East Africa where it caused a febrile illness associated with one or more poxviruslike lesions, but the virus has also been isolated in Zaire and may be present across tropical Africa. The natural host is uncertain but the ability to cause disease only in monkeys would be consistent with a simian origin. Serological evidence of infection in African monkeys (Tsuchiya and Tagaya 1971; Downie 1974) established that these animals may be infected, but it remains unclear if monkeys are the natural host, or whether infections in monkeys are zoonoses after transmission from another reservoir. Human infections were more common close to rivers or following periods of flooding suggesting transmission by a biting arthropod. YMTV causes histiocytomas in rhesus monkeys and man (Niven et al. 1961).

POXVIRUSES AND BIOTERRORISM

The terrorist attacks in Washington DC and New York in 2001 and the subsequent release of anthrax spores in the USA prompted an urgent evaluation of whether there was adequate preparation against microbial pathogens that might be used in bioterrorism. If terrorists were prepared to commit suicide and mass murder by flying aeroplanes into civilian populations, it seemed probable that they might also be willing to obtain, grow, and release pathogenic micro-organisms. Top of the list of potential bioterror agents was variola virus. At the end of 2001, the preparedness for a smallpox epidemic was far from adequate. Smallpox vaccination had been discontinued for approximately 30 years and so roughly 40 percent of the population was immunologically naive for orthopoxviruses. Furthermore, it was uncertain if those vaccinated several decades previously had retained sufficient immunity to provide protection against variola virus. The stocks of vaccine were both old and limited. Indeed, during the 1990s, the World Health Organization (WHO) had ordered the destruction of millions of doses of vaccine that were deemed no longer required. The release of variola virus in a densely populated public place, perhaps a center of public transportation, might cause infection of many citizens. Given that smallpox takes an average of 11 days to develop following infection, those infected might have traveled far and wide and disseminated the infection to others before the outbreak was realized. Faced with this situation, health authorities would have an immensely challenging task of identifying all those exposed initially and all the contacts of those exposed. It was likely that the supply of vaccine would rapidly become exhausted.

Faced with this scenario, several governments initiated programs to replenish their stocks of smallpox vaccine, to increase surveillance for smallpox and to vaccinate some of their citizens. The US Government purchased sufficient vaccine to immunize each of its citizens and vaccination programs were initiated to protect approximately 500 000 first-line responders during the first quarter of 2003, approximately 11 million by the end of 2003 and, possibly, the whole population thereafter. In other western countries, the response was less radical. The UK Government vaccinated only 350 healthcare workers (www.doh.gov.uk) and bought sufficient vaccine to immunize the population if there were an outbreak. Elsewhere in Europe, some governments simply purchased vaccine, but did not vaccinate their citizens.

The decision not to vaccinate large fractions of the population was driven mostly by the fears of complications with the existing smallpox vaccines. During mass smallpox immunizations, it was recognized that immunization could cause complications such as progressive vaccinia, eczema vaccinatum, and neurological conditions with a death rate of approximately 1–5 per million vaccinees (Lane et al. 1969; Feery 1977). Those with immunological deficiency or eczema were more susceptible and pregnancy was also a condition that increased the risk of complications or their severity (Fenner et al. 1988). Today, the frequency of complications would probably be greater because a significant fraction of the population is immunosuppressed due to HIV infection and more people have eczema. In view of this, and to minimize the risk of complications, potential vaccinees

(and their close contacts) were screened carefully for contraindications to vaccination and vaccinees were monitored after vaccination. Despite this, complications occurred in the USA and the vaccination program has largely halted after approximately 500 000 vaccinations. An unexpectedly frequent complication was myocarditis (Cassimatis et al. 2004) that had been reported more rarely during previous smallpox vaccination programs (Feery 1977).

The strain of vaccine to be used in the new vaccination programs and to be stockpiled for national reserves was a source of contention. The smallpox vaccines strains that were widely used to achieve global eradication were Lister and New York City Board of Health (Wyeth) and these were effective at preventing smallpox by all strains of variola virus. Although, these vaccines were known to be effective, they were also known to have an imperfect safety record (Lane et al. 1969; Feery 1977). These vaccines had similar rates of complication, although precise comparisons are difficult because of differing populations in which these vaccines were used and different methods of assessing complication rates. Alternative vaccines based upon more attenuated strains of vaccinia virus such as LC18m8 in Japan (Hashizume et al. 1985) and modified virus Ankara (MVA) in Germany (Stickl et al. 1974) had been developed and shown to be safer in man, but their effectiveness at preventing smallpox was unproven because those immunized were never exposed naturally to variola virus. Faced with the choice of using an established vaccine that worked but caused complications, or a safer vaccine that was not proven to be effective, most governments bought the old vaccine. However, these new stocks of vaccine stocks were manufactured under modern good manufacturing practice conditions (in some cases after plaque purification) in sterile tissue culture and with rigorous screening for exogenous pathogens. In contrast, the old smallpox vaccines had been grown on the side of sheep or cattle and contained significant bacteriological contamination.

In countries where a cohort of first-line responders has been vaccinated, who would be able to treat smallpox patients without contracting and spreading the disease, there will be a need to maintain vaccination for as long as the perceived threat of smallpox remains. WHO recommended revaccination every 3 years for those in areas where smallpox was endemic.

ANTI-POXVIRUS DRUGS

The availability of an effective vaccine against smallpox was a disincentive for the development of effective drugs for combating smallpox or other poxvirus infections. However, the worries of bioterrorism and the potential to enhance the virulence of pathogenic poxviruses by genetic engineering (Jackson et al. 2001) have increased the need for effective drugs. Recent drug screening programs have identified several potentially useful drugs. The first of these is cidofovir, a licensed antiherpes virus drug used to combat human cytomegalovirus infections. Cidofovir prevents replication of many orthopoxviruses (including variola virus) in cell culture and can protect against orthopoxvirus infection in animal models (Bray et al. 2000). There are some disadvantages to cidofovir, however, such as renal toxicity and the need for the drug to be administered by intravenous injection. These difficulties are being overcome by the development of chemically modified versions of cidofovir. These can be taken orally, have enhanced activity against poxviruses, and, importantly, are no longer toxic for kidneys (Ciesla et al. 2003) but accumulate in the respiratory system, the site of primary infection by variola virus. Preliminary animal experiments show that the drug can protect against orthopoxviruses in vivo (Buller et al. 2004).

Cidofovir's mode of action is by inhibition of the virus DNA polymerase, but other virus proteins that are essential for virus replication are also being considered as targets for antipoxvirus drugs. These include dUTPase, topoisomerase, and proteins critical for virus morphogenesis. With all of these new drugs, although it will be possible to determine if they can protect against orthopoxviruses in animal models, it will be impossible to demonstrate efficacy against smallpox in man. This poses a regulatory problem for licensing.

IMMUNE RESPONSE TO SMALLPOX VACCINATION

During the smallpox eradication campaign, the immune response to vaccination had been evaluated with techniques that by today's standards were primitive. Moreover, the importance of immunity to the antigens specific to the EEV had not been fully appreciated and the immune response was evaluated predominantly against IMV. Tests such as hemagglutination inhibition (HAI), complement fixation, and plaque neutralization were employed, although the latter test was almost invariably performed against IMV. However, it was known that although vaccines composed of inactivated IMV induced very good levels of neutralizing antibody to IMV in man or animals, they failed to confer protection because they did not induce immune response to EEV antigens, for reviews see (Boulter and Appleyard 1973; Smith et al. 2002). Overall, there was only a rudimentary understanding of the immunological responses to smallpox vaccination and there was no clear benchmark that correlated with protection from smallpox. Instead a recent vaccination scar (within 3 years) was considered the best evidence.

Against this background, the recent smallpox vaccination programs in the USA and UK have provided an

opportunity to evaluate the response to smallpox vaccination using modern immunological techniques. These have included measurement of both cell-mediated and humoral immunity and have analyzed the antibody responses to IMV, EEV, and specific antigens from either virion. This is providing a benchmark against which the immunity remaining in individuals immunized decades previously or the immune response induced by new smallpox vaccines can be compared. An encouraging finding is that the immunological responses to vaccination are retained for several decades (Hammarlund et al. 2003; Terajima et al. 2003), although there must be caution in interpreting this as evidence of protection against smallpox.

The continuing worry about smallpox and bioterrorism, and the inadequate safety profile of traditional smallpox vaccines is prompting more research to develop safer vaccines. Strains LC16m8 and MVA are both being evaluated. MVA, in particular, shows promise. It was established that primary infection with MVA is safe in man and that this primary vaccination would cause the response to a subsequent vaccination with conventional vaccine to be modified, indicating existing immunity. MVA can also induce protection against challenge with other orthopoxviruses, such as vaccinia or monkeypox in rodent and animal models (Drexler et al. 2003; Earl et al. 2004). However, its efficacy in man remains unproven and a recent report showed that two immunizations with MVA induced inferior protection against monkeypox virus challenge than a single immunization with a conventional vaccine (DRYVAX) (Earl et al. 2004).

LC16m8 also has a good safety record in man and primary vaccination induced less severe reactions than those induced by the Lister strain from which LC16m8 was derived (Hashizume et al. 1985). However, a potential difficulty with LC16m8 is a mutation in the B5R gene that prevents expression of the B5R protein (Takahashi-Nishimaki et al. 1991). As well as being required to make a normal plaque size, B5R has been identified as the only EEV-specific protein that is the target for antibodies that neutralize EEV infectivity (Galmiche et al. 1999; Law and Smith 2001; Hooper et al. 2003). Given that responses to EEV are important for protection against orthopoxviruses, the omission of *B5R* is a potential problem for this vaccine. It would seem logical in the design of new smallpox vaccines to include this antigen.

POXVIRUS CLASSIFICATION AND VIRION STRUCTURE

Poxviruses are one of the most complex DNA-containing virus families. The strategy for growth and reproduction of this family of viruses is sufficiently robust and adaptable to have become established in a variety of eukaryotic hosts from insects, birds, and reptiles to higher vertebrates including man. Taxonomically, the *Poxviridae* family comprises two subfamilies: the *Chordopoxvirinae* (viruses of vertebrates) and the *Entomopoxvirinae* (viruses of insects) (Moyer et al. 2000) (Table 1). There are eight *Chordopoxvirinae* genera: *orthopoxvirus*, *Parapoxvirus*, *Avipoxvirus*, *Capripoxvirus*, *Leporipoxvirus*, *Suipoxvirus*, *Molluscipoxvirus*, and *Yatapoxvirus*, of which four (*orthopoxvirus*, *Parapoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus*) can cause human infections. Of these, the most clinically significant diseases are those caused by the orthopoxvirus *Variola virus* (VARV) (smallpox) and *Monkeypox virus* (MPXV), and the molluscipoxvirus *Molluscum contagiosum virus* (MOCV) (Esposito and Fenner 2001). There are three genera of entomopoxviruses, designated A, B, and C, based mainly on host range. Many entomopoxviruses await further classification.

Poxvirus family members share a number of unique features including:

- a large complex enveloped virion that appears as an enveloped, brick-shaped structure and is of sufficient size to be visualized under a light microscope
- the packaging in virions of a variety of enzymes including all those required to carry out transcription of poxvirus early genes from the DNA contained within the virus
- a cytoplasmic site of replication
- a double-stranded genomic DNA which can range in size from approximately 144 kb (Yaba-like disease virus, Lee et al. 2001) to nearly 300 kb (*Fowlpox virus*, Afonso et al. 2000) and up to nearly 400 kb for some entomopoxviruses (Moyer et al. 2000)
- a hairpin loop of DNA comprised of imperfectly paired heteroduplex DNA present at both termini of the genome
- a complex mechanism for assembly of infectious virions.

The overall virus growth cycle is depicted in Figure 1 p. 3 and will be expanded upon throughout this chapter.

Vertebrate poxviruses also share a co-linear core of conserved genes located within the central-most region of the genome (Figure 2 p. 3). These core genes comprise about 60 percent of the coding capacity of the virus. They are generally required for virus growth and are thus associated with essential virus functions such as transcription and DNA replication. On the other hand, the 'variable regions,' comprising the remainder of the genome extending to both termini, contain genes many of which are not essential for growth, including those devoted to control of host range as well as the responses of the cell or animal host to infection. While entomopoxviruses also contain most genes of the common

Table 1 *Family* Poxviridae *taxonomy*

Subfamilies	Genera	Member viruses	Features
Chordopoxvirinae	*Orthopoxvirus*	Camelpox,[c] cowpox,[c] ectromelia,[c] MPXV,[c] raccoonpox, skunkpox, Uasin Gishu,[a] vaccinia,[b,c] variola,[c] volepox	Brick-shaped virion, DNA ca. 200 kbp, G+C ca. 36%, wide to narrow host range, variola (smallpox), vaccinia (smallpox vaccine)
	Parapoxvirus	Auzduk disease,[a] chamois contagious ecthyma,[a] orf,[b] pseudocowpox, parapox of deer, sealpox[a]	Ovoid virion, DNA ca. 140 kbp, G+C ca. 64%
	Avipoxvirus	Canarypox, fowlpox,[b,c] juncopox, mynahpox, pigeonpox, psittacinepox, quailpox, peacockpox,[a] penguinpox,[a] sparrowpox, starlingpox, turkeypox	Brick-shaped virion, DNA ca. 260 kbp, G+C ca. 35%, birds, arthropod transmission
	Capripoxvirus	Goatpox, lumpy skin disease, sheeppox[b]	Brick-shaped virion, DNA ca. 150 kbp, ungulates, arthropod transmission
	Leporipoxvirus	Hare fibroma, myxoma,[b,c] rabbit fibroma,[c] squirrel fibroma	Brick-shaped virion, DNA ca. 160 kbp, G+C ca. 40%, leoporids and squirrels
	Suipoxvirus	Swinepox[c]	Brick-shaped virion, DNA ca. 170 kbp, narrow host range
	Molluscipoxvirus	MOCV	Brick-shaped virion, DNA ca. 180 kbp, G+C ca. 60%, human host, localized tumors, contact spread
	Yatapoxvirus	Tanapox, Yaba monkey tumor[b]	Brick-shaped virion, DNA ca. 145 kbp, G+C ca. 33%, primates and ? rodents
Entomopoxvirinae	*Entomopoxvirus A*	Melontha melontha[b]	Ovoid virion, DNA ca. 260–370 kbp, Coleoptera
	Entomopoxvirus B	Amsacta moorei[b,c]	Ovoid, DNA ca. 236 kbp, G+C ca. 18%, Lepidoptera and Orthoptera
	Entomopoxvirus C	Chrionimus luridus[b]	Brick-shaped virion, DNA ca. 250–380 kbp, Diptera
	Unclassified	Melanoplus sanguinipes[c]

c) Completely sequenced.

vertebrate poxvirus core, the genes are not conserved in the typical co-linear vertebrate virus core fashion, but rather are dispersed throughout the genome. The significance, if any, of the altered organization pattern in entomopoxviruses is not clear.

In the case of vertebrate viruses, while the diseases caused by individual viruses can vary greatly, the molecular events which govern basic functions such as transcription, DNA synthesis, and morphogenesis are quite similar. What distinguishes individual viruses physiologically, and is likely responsible at least in part for the distinct clinical syndromes, are the genes associated with host range and the different sets of immunomodulatory genes, found mainly in the variable regions of the genome. Much of what we know about *orthopoxvirus* genes of this nature has been derived from studies with Vaccinia virus. We will discuss some of these host range and immunomodulatory genes later in this chapter.

Some comment on the poxvirus gene nomenclature used for this chapter is in order. The first poxvirus genome to be sequenced in its entirety was vaccinia Copenhagen (Goebel et al. 1990). The open reading frame (ORF) designations adopted for the Copenhagen sequence were based on the *Hin*dIII restriction map of the genome and the direction of transcription. For example, the viral DNA topoisomerase was designated as H6R, the sixth ORF from the left end of the *Hin*dIII H DNA fragment, transcribed in a rightward direction. Because it was the first complete vaccinia sequence available, the Copenhagen nomenclature became the standard in the field. However, the vaccinia strain WR has been the de facto strain used for experimentation for more than 30 years, even though the complete WR genome sequence only recently became available. Recent nomenclature rules adopted by the International Committee on Taxonomy of Viruses (ICTV) and applied to the more recently sequenced poxvirus genomes uses a linear designation beginning at the left-hand end of the genome and continuing to the right end of the genome. Using the newer nomenclature, the WR ortholog of the vaccinia Copenhagen *H6R* gene is

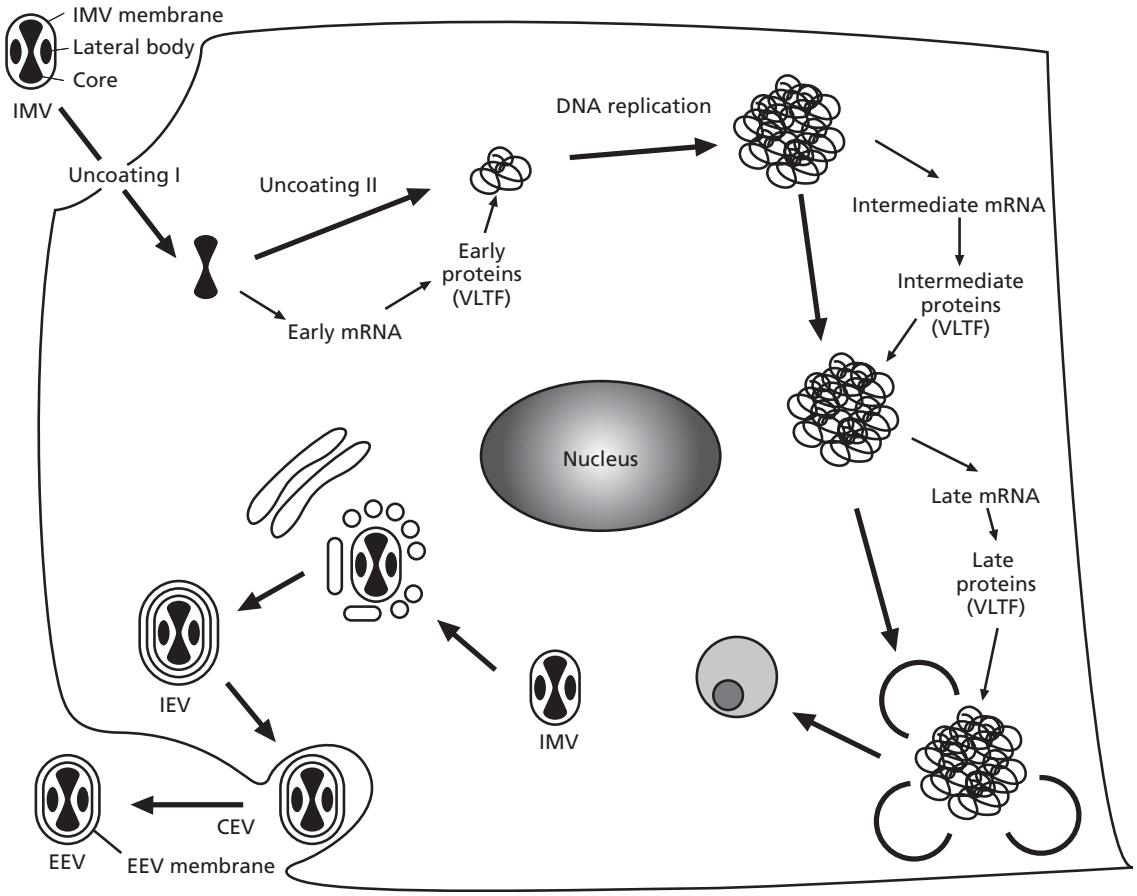

Figure 1 *The poxvirus growth cycle. Features of growth shared by all poxviruses include a temporal pattern of gene expression, a cytoplasmic site of development. Orthopoxviruses, such as variola virus and vaccinia virus, produce two distinct forms of virions. Initially, IMV is the first infectious virus formed. A small portion of that virus is wrapped within two additional layers of Golgi-derived membranes to form IEV. IEV is externalized by fusion of the outermost membrane of IEV with the plasma membrane of the cell to form CEV. CEV released from the cell surface produces free EEV. CEV, cell-associated enveloped virus; EEV, extracellular enveloped virus; IEV, intracellular enveloped virus; IMV, intracellular mature virus; VETF, viral early transcription factors; VITF, viral intermediate transcription factors; VLTF, viral late transcription factors.*

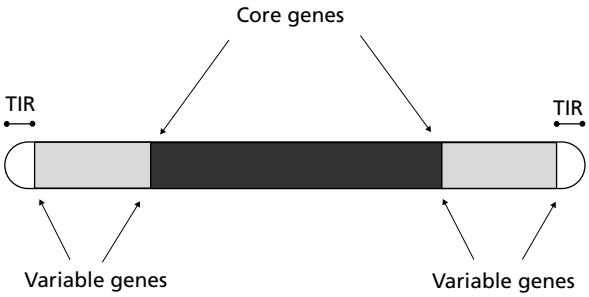

Figure 2 *The genetic organization of vertebrate poxviruses. The poxvirus is comprised of double-stranded DNA but is variable, ranging from 130 to 330 kb in individual viruses. The central-most region of the viral chromosome contains a generally conserved linear core of genes, most of which are shared by all vertebrate poxviruses. Genes within the regions to the left and right of the core gene region are the most variable and serve to distinguish the individual members of the family. Genes within this region tend to be virus-specific. The termini of the genome are highlighted by imperfectly paired TIRs. The two DNA strands are linked, resistant to exonuclease digestion, and thus form a loop or hairpin.*

designated as *VACV-WR_104*. So while acknowledging the history of the field and the use of Copenhagen nomenclature in much of the literature to date, yet mindful that vaccinia WR is the prototypic vaccinia strain and that nomenclature procedures have been changed, we have designated ORFs by both the original Copenhagen and the newer vaccinia WR designations where possible.

Virions and virion structure

The poxvirus virion structure is both unique and unconventional compared to other viruses. In general, poxvirus virions bear none of the classical features of a helical or icosahedral nucleocapsid, and while they are enveloped, the structure and biogenesis of the envelope is unusual.

Mature poxvirus virions exist in four forms which differ in the number of membranes and hence surface antigens surrounding the particle (reviewed by Smith et al. 2002). The four forms are designated intracellular

mature virus (IMV), intracellular enveloped virus (IEV), cell-associated enveloped virus (CEV), and extracellular enveloped virus (EEV) (Figures 1 and 11). IMV, the first assembled and simplest infectious form of virus, is a membraned particle that, as the name implies, remains inside cells following virus maturation (Boulter and Appleyard 1973). IEV is an intermediate in the formation of CEV and EEV, these latter two being infectious extracellular forms of virus. IEV is essentially IMV that has acquired two additional membranes via wrapping in Golgi-derived cisternae (Ichihashi et al. 1971). CEV is derived from IEV by fusion of the outermost IEV membrane with the plasma membrane (Blasco and Moss 1992). CEV is thus essentially an IMV particle that is wrapped in one additional lipid bilayer and that remains attached to the outer surface of the cell. EEV is CEV that has been released from the surface of the cell (Boulter and Appleyard 1973). IEV contains an additional seven membrane proteins not found in IMV, while CEV and EEV each contain five of these seven proteins (Smith et al. 2002). Although it is a membraned particle, IMV is extraordinarily stable, and therefore presumably provides the virus with a mechanism for maintaining infectivity in the environment between hosts over long periods of time. EEV and CEV are thought to be critical for cell-to-cell spread during infection. Thus, collectively, the multiple forms of poxviruses encompass all of the advantages of both enveloped and non-enveloped viruses.

EEV is experimentally distinguished from IMV based on antigenic differences due to the presence of different surface components, and by the fact that the extra lipid envelope confers a lighter buoyant density to the EEV particle compared to IMV (reviewed by Smith et al. 2002). The distinction between the various forms of virus is also clinically significant. It has been proposed that prevention of disease caused by orthopoxviruses is primarily related to EEV particles rather than IMV. For example, during the smallpox eradication program, some vaccines were prepared from inactivated virus obtained following disruption of infected cells (IMV). These vaccines were largely ineffective in preventing orthopoxvirus infections in humans (Kaplan 1962; Kaplan et al. 1962, 1965). Indeed, the relative efficacy of anti-IMV and EEV antisera to prevent spread of the IMV-induced infections in animals has clearly shown that anti-EEV antibodies are of much greater benefit even when there is a subsequent virus challenge (Boulter et al. 1971; Boulter and Appleyard 1973). Although EEV production is typically low compared to IMV, there are two experimental methods by which to assay and verify the presence of EEV. The first is the test for 'comets' (Law et al. 2002) where strains that produce high levels of EEV, such as vaccinia strain IHD (International Health Division) or rabbitpox virus (RPV), are allowed to grow on cell monolayers in the absence of the typical agar overlay. Such strains will generate 'comet-shaped' rather than spherical plaques, resulting from release of EEV from the primary plaque and spread of the infection to distant sites on the monolayer. Comets are inhibited by antisera to EEV but not IMV. The second method represents a modified neutralization assay in which EEV is pretreated with antibody against inactivated IMV. EEV escapes neutralization by this antibody and will produce a plaque when titered.

The structure of intact IMV, the simplest and predominant form of the virus, has been extensively studied by electron microscopy (EM). Analysis of whole virions by cryo-electron microscopy, which is thought to preserve best the natural surface features of the virion, reveals a rectangular structure with dimensions of 350×270 nm, including a 30 nm thick 'surface domain' which is less electron dense relative to the inner domain of the particle (Figure 3) (Dubochet et al. 1994; Griffiths et al. 2001b). By contrast, conventional EM of negatively stained, dehydrated samples of purified IMV reveal numerous rodlike protrusions, called surface tubule elements (STE), on or near the surface of the virion (Figure 3) (Wilton et al. 1995). Cross-sections of IMV reveal four distinct virion substructures: the envelope, the lateral bodies, the core wall, and the core (Figure 3) (Dales and Pogo 1981; Ichihashi et al. 1984; Griffiths et al. 2001a, 2001b). In many sections, the core and its wall possess a biconcave dumbbell or peanut shape; however, in many sections the core appears round, rectangular, or even somewhat irregularly shaped, ultimately suggesting a three-dimensional structure similar to an elongated biconcave disk. The core wall is a bilaminar structure, with an inner smooth layer approximately 5 nm thick and an outer layer, sometimes referred to as the 'palisade layer,' made up of regularly arranged projections approximately 10 nm in length and 5 nm in diameter (Easterbrook 1966). The lateral bodies are uniform in electron density and fill the space between the concavities in the core and the envelope. The envelope, which contains the lipid outer membrane, is also a bilaminar structure, with an inner layer approximately 5 nm thick and an outer layer approximately 9 nm thick (Hollinshead et al. 1999).

IMV substructure

The precise biochemical make-up of the poxvirus virion has been investigated by controlled degradation of purified virions coupled with deductions made from studies of virus assembly. Virions contain as many as 100 proteins, most, if not all, of which are virus coded (Essani and Dales 1979; Jensen et al. 1996). The precise substructure of the virion envelope is controversial: while some studies conclude that the envelope contains a single lipid bilayer, others conclude that it contains two tightly apposed bilayers (Hollinshead et al. 1999; Sodeik and Krijnse-Locker 2002) (see section on Poxvirus morphogenesis: IV and IMV membrane formation, below).

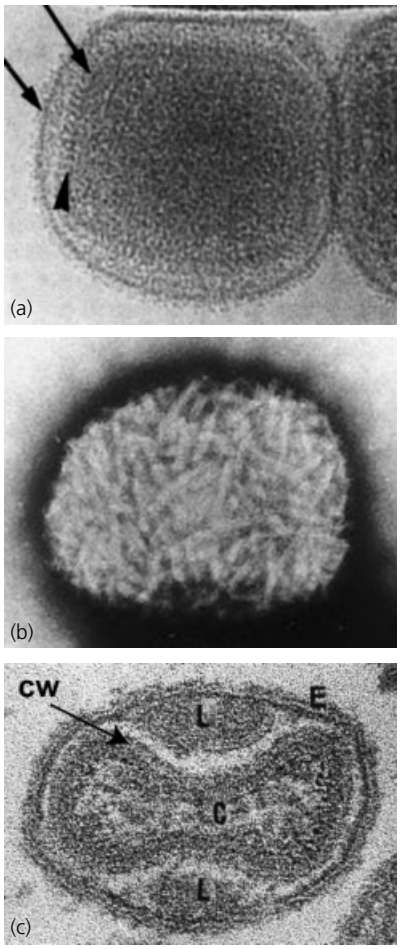

Figure 3 *Vaccinia virion structure.* **(a)** *Cryo-election microscopy of positively stained isolated particles. Two layers are evident (arrows) that are separated by a spike or spicule layer (arrowhead).* **(b)** *Negatively stained isolated particles showing surface tubule elements.* **(c)** *Thin section of a vaccinia virion showing envelope (E), lateral bodies (L), and the core (C) surrounded by the core wall (CW).* **(a)** *is reproduced from Griffiths et al. 2001b;* **(b)** *from Wilton et al. 1995;* **(c)** *from Pogo and Dales 1969.*

Treatment of virus with neutral detergent and a reducing agent solubilizes the envelope and as many as a dozen envelope-associated proteins (Easterbrook 1966; Ichihashi et al. 1984; Jensen et al. 1996). Under appropriate conditions, some of these solubilized proteins are contained in tubular structures which may be equivalent to the STEs seen in dehydrated, negatively stained intact IMV (Wilton et al. 1995). Several of the IMV envelope proteins exist in a disulfide-bonded complex (Rodriguez et al. 1997). Upon solubilization of the outer envelope, the virion core, which now assumes a more rectangular or brick-shaped structure, can be isolated with the lateral bodies still attached (Easterbrook 1966). The lateral bodies can be removed with controlled trypsin treatment and therefore are proteinaceous in nature. The exact chemical composition of the core wall is unclear. While some investigators contend that the core wall contains a true lipid bilayer (or two tightly apposed bilayers), others argue that it contains no lipid (Wilton et al. 1995; Griffiths et al. 2001b). At least one of the major virion structural proteins, 4b, localizes to the outer surface of the core wall (Ichihashi et al. 1984; Wilton et al. 1995). Within the core resides the viral DNA complexed with several virus-coded DNA-binding proteins (Ichihashi et al. 1984).

Because poxviruses initiate infection and thereafter express information from a DNA molecule in the cell cytoplasm, the virions contain the full complement of enzymes required for synthesis of early viral mRNA. Virion cores are thus a rich source of the viral enzymes necessary for viral transcription and modification (Kates and McAuslan 1967; Kates and Beeson 1970a; Shuman and Moss 1990) (Table 2). The subviral core is capable of synthesizing authentic early viral mRNAs in vitro which are capped, methylated, and polyadenylated (Kates and Beeson 1970b; Wei and Moss 1975; Bossart et al. 1978; Pelham et al. 1978). The enzymology of viral mRNA metabolism is discussed in detail below (see section on Poxvirus transcription and regulation of viral gene expression). The precise localization and organization of viral enzymes within the core is not known. Presumably, as the virus particle transverses the cellular membrane during the entry process, partial uncoating of the intact IMV must occur, thereby creating the transcriptionally active core (Pedersen et al. 2000).

In addition to the enzymes and factors listed in Table 2, which have an obvious direct role in RNA metabolism, the virion contains other enzymes with activities suggesting roles in nucleic acid or protein modification (Table 3). These include a topoisomerase (H6R/VACV-WR_104), an RNA helicase (I8R/VACV-WR_077), two protein kinases (F10L/VACV-WR_049 and B1R/VACV-WR_183), a protein phosphatase (H1L/VACV-WR_099), a glutaredoxin (O2L/VACV-WR_069), and three thiol oxidoreductases (G4L/VACV-COP_099, E10R/VACV-COP_082, and A2.5L/VACV-WR_121). Mutants in the RNA helicase are defective in the virus core-directed in vitro transcription reaction in a fashion which suggests that the RNA helicase may play a role in transporting newly synthesized early viral mRNA out of the core particle (Gross and Shuman 1996). For reasons unknown, mutants in the H1L phosphatase are also defective in early viral transcription (Liu et al. 1995). The F10L protein kinase seems to play a role in regulation of virion morphogenesis via phosphorylation, discussed in more detail below (see section on Poxvirus morphogenesis: IV and IMV membrane formation) (Traktman et al. 1995). The B1R kinase plays an essential role in viral DNA replication, discussed in more detail below (see section on The structure and replication of poxvirus DNA: The enzymology of DNA replication) (Rempel and Traktman 1992). While the O2L glutaredoxin is nonessential, the G4L, E10R, and A2.5L thiol reductases form a complex which comprises a complete disulfide-bonding pathway which targets at least two other vaccinia

structural proteins and is essential for successful virion morphogenesis (Senkevich et al. 2002). While the biochemistry of the topoisomerase is understood in exquisite detail, the role of this enzyme in poxvirus replication is not known because no virus mutants in the *H6R* gene have been isolated (Tian et al. 2003).

THE STRUCTURE AND REPLICATION OF POXVIRUS DNA

The structure of poxvirus DNA

There are several observations and structural features relevant to poxvirus DNA replication which must be considered within the context of replication. First is the rather unusual structure of the viral DNA, which is comprised of linear double-stranded DNA, terminating in inverted repeats linked through an imperfectly paired DNA 'loop' or 'hairpin' (Figures 2 and 31.4a). Second, during the process of replication, concatemeric intermediates are formed, necessitating the need to excise functional monomeric molecules as well as to recreate the terminal hairpins or loops at the end of the genome. Third, consistent with the cytoplasmic nature of these viruses, DNA replication does not occur within the nucleus, which demands that the virus encode a variety of replicative enzymes whose cellular equivalents are confined to the nucleus.

a) Enzymes in this table are those that have not been shown to play a direct role in transcription. See Table 2 for virion transcription enzymes.
b) Multiple genes indented under a single enzyme/factor designates a multisubunit enzyme/factor.
c) See text for description of nomenclature. Many genes do not have a 'common' name; thus only the Copenhagen and WR designations are used.
d) A single reference is given which identifies the gene or assigns a function. See text for additional references.

The terminal most region of DNA comprising the hairpin or loop abuts a series of tandem repeats of various sizes (Figure 4b). The DNA within the hairpin or loop per se that 'caps' the larger terminal inverted sequence region (TIR) serves to link the two complementary strands and creates a telomere comprised of an imperfectly paired A+T-rich region of DNA (Figure 4b, c). The hairpins exist in two forms, sometimes call 'flip' and 'flop,' which are perfect inverse complements of each other, such that when base paired with each other they form a perfect duplex (Figure 4c, d). The duplexed flip and flop hairpins form the junction between concatemers (Figure 4d), and have important implications in the mechanism of DNA replication described below. Following and next to each terminal hairpin, the TIRs present at both the left and right extremes of the molecule continue inward. The total length of TIRs can vary from as little as 58 bp in variola virus (Shchelkunov et al. 1995) to more than 12 kb in Shope fibroma virus, a *Leporipoxvirus* (Willer et al. 1999). Indeed, there is at least one example where the TIRs have been shown to exhibit marked variation in size and sequence (up to 30 kb) from different plaque isolates of one virus (Figure 5) (Moyer and Graves 1981). A possible mechanism for the generation of variable TIRs is discussed later in the chapter. Because the TIR sequences are by definition repeated at both termini of the genome, ORFs contained within the TIRs are diploid. The sequences at the very left or right extremes of the TIRs nearest the hairpin which contain the series of small tandem, conserved repeats also contain a sequence which serves as a 'nicking site' to initiate the DNA replication process. This nicking site may also be involved in the maturation of mature length molecules from replicative DNA concatemeric intermediates (Moyer and Graves 1981). Viral DNA concatemers are not only a key feature and intermediate in poxvirus genome replication but they also allow for rapid evolution, adaptation, and diversity at the terminal extremes of the molecule which in turn constitute the primary genetic distinctions among individual poxviruses.

Several additional features of the general organization of individual poxvirus genes are noteworthy. All genes are uninterrupted, linear, and without introns. Generally, there is little overlap between individual genes. While transcription of genes can occur in either direction, genes at the termini of the viral chromosome tend to be transcribed predominantly towards the end of the chromosome.

The mechanism of DNA replication

DNA replication not only serves to provide DNA for progeny virus but also provides a functional template for the temporal expression of intermediate and late

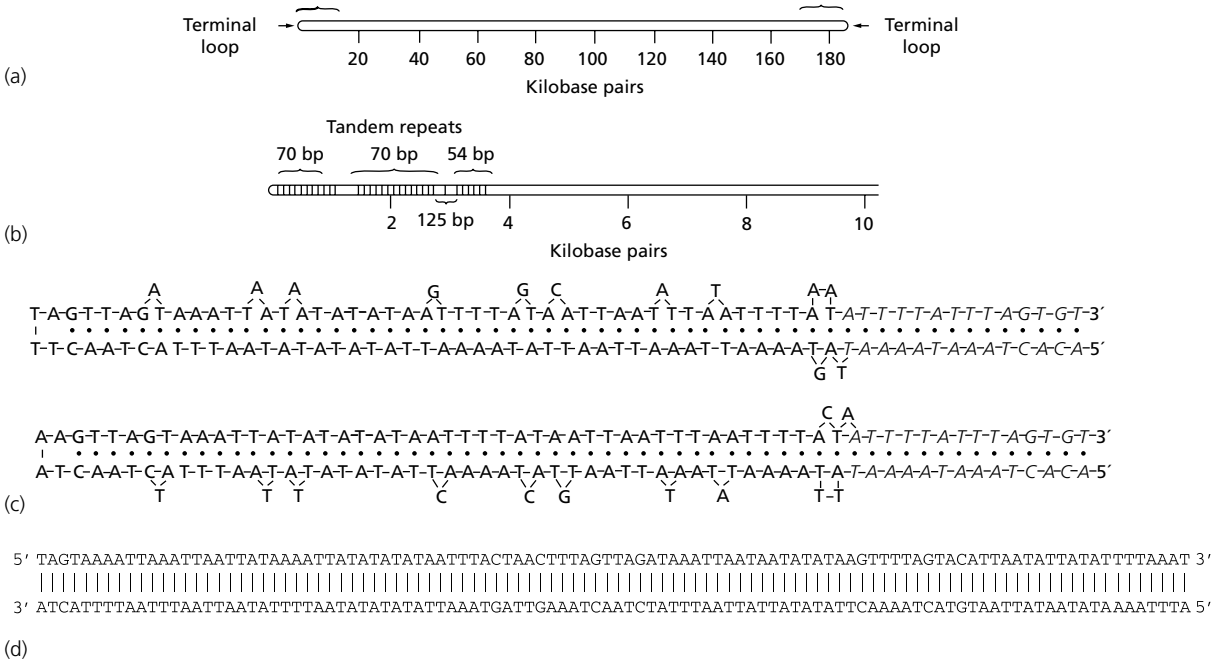

Figure 4 *Structural features of the vaccinia virus genome. From the top down is shown:* **(a)** *a unit length genome emphasizing size, inverted terminal repetition, and hairpin (terminal) loops;* **(b)** *an enlargement of the inverted terminal repeat, emphasizing the tandem repeats within the terminal repeat;* **(c)** *the two hairpin loops (non-italic font) as they are joined to the terminal repeats (italic font);* **(d)** *the duplex structure formed at a concatemer junction, consisting of the unfolded hairpins base paired to each other. viral genes. Synthesis of DNA occurs within the cytoplasm and is readily visualized by electron microscopy as electron-dense bodies or 'factories' which serve as the site of initiation for the assembly of mature virions. The mechanism of DNA synthesis takes into consideration the following features of viral DNA already discussed: the TIRs, the terminal DNA hairpin loops, and the generation of replicative concatemeric DNA.

The onset of replication is heralded by introduction of a nick within one or both inverted terminal repeats (ITR), most likely within 200 bp of the end of the molecule (Du and Traktman 1996). The nicking can occur at either or both termini, but for simplicity is only shown at one end (Figure 6). Strand extension at the 3′ terminus of the nick with concomitant strand displacement allows the terminal nucleotides to be copied. Hybridization of the newly synthesized terminal-most nucleotides to the parental strand leads to formation of flip and flop hairpins (Figure 4c; Baroudy et al. 1982). Thereafter polymerization continues, eventually giving rise to concatemers comprising complete genomic units of fused head-to-head or tail-to-tail genome length monomers (Moyer and Graves 1981). Additional complexity can be conferred to replicating DNA through either strand invasion by other molecules, by initiating a second replication cycle on molecules actively replicating or through recombination. There are a number of biochemical studies consistent with the proposed mechanism.

Concatemeric DNA must be resolved and unit length genomes excised in order to assemble mature virus. A graphic illustration of a possible mechanism for this process is shown in Figure 7, p. 12, in which resolution is initiated by a sequence-specific nick. The detailed requirements for concatemer resolution include a small recognition cleavage sequence (Delange et al. 1986; Merchlinsky and Moss 1986, 1989) present as an inverted repeat on both sides of the fused RR or LL hairpin loop contained within the L–RR–LL–R head-to-head or tail-to-tail concatemers that results from the replication process. It has been proposed that resolution may also occur via site-specific recombination and oriented branch migration (Merchlinsky 1990), or by nicking and sealing of extruded cruciform, holiday-like structures (McFadden et al. 2003).

It is possible for concatemers to exist as large cruciform structures and deletions can readily occur within such structures. During genome maturation, such deletion events allow for expansion and contraction of the terminal regions of the chromosome and creation of TIRs of varying length as described (Figure 8, p. 13). The terminal variability is theoretically limited only by the need to retain the essential genes in or at the conserved core and the *cis*-sequences required for replication (Moyer et al. 1980; Moyer and Graves 1981) and provides a mechanism for rapid evolution of genes within this region. The documented ability of terminal regions of the virus to expand and contract implies that

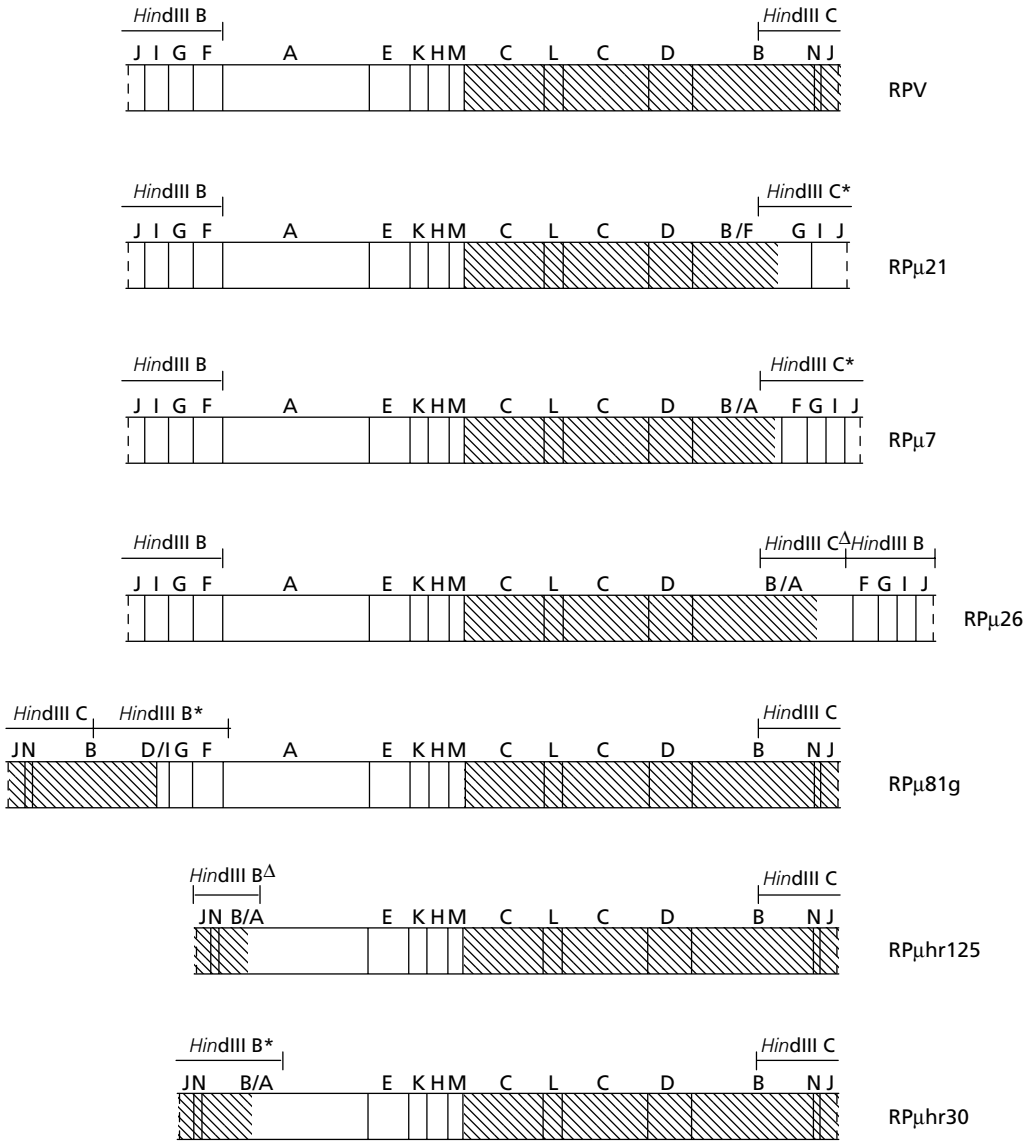

Figure 5 *Variation in size of poxvirus terminal repeats. The* XhoI *maps of RPV and six TIR variants are shown. The genome of RPV and all variants are sized to scale. Genome sizes are drawn to scale. The right and left halves of the parental RPV genome are distinguished by shading. The mutants RPμ21, RPμ7, and RPμ26 have expanded terminal repeats derived from the left region of wild-type RPV. The TIRs of RPμ26 are sufficiently large to contain many functional genes. The mutants RPμ81g, RPμhr125, and RPμhr30 likewise have expanded terminal repeats compared to wild-type RPV (from Moyer and Graves 1981). The generation of expanded TIRs through duplication and transposition of either left or right regions of the genome is likely a consequence of replication (see text).*

the amount of DNA packaged within a virion is not fixed and is determined by the location of the concatemer resolution sequences rather than the amount of DNA within a given chromosome. Indeed, it has been shown the amount of DNA packaged can be far larger than the minimum genome normally associated with a given virus and the entire bacteriophage lambda chromosome can be stably maintained within vaccinia virus (Smith and Moss 1983). This genomic plasticity has been exploited in the creation of a wide variety of recombinant poxviruses with large inserts of foreign DNA for a variety of applications.

The enzymology of DNA replication

Although poxviruses encode many enzymes associated with aspects of DNA synthesis, those that are conserved among many members are likely to constitute the 'basic' or core replication machinery (Table 4, p. 14). A subset of these conserved proteins, have been shown through the study of mutants, to exhibit defects in DNA synthesis (Table 4, top). The role of other conserved genes is in post-synthetic steps of DNA maturation or is unknown. The subset of proteins known to be involved in DNA synthesis include a DNA polymerase (ORF

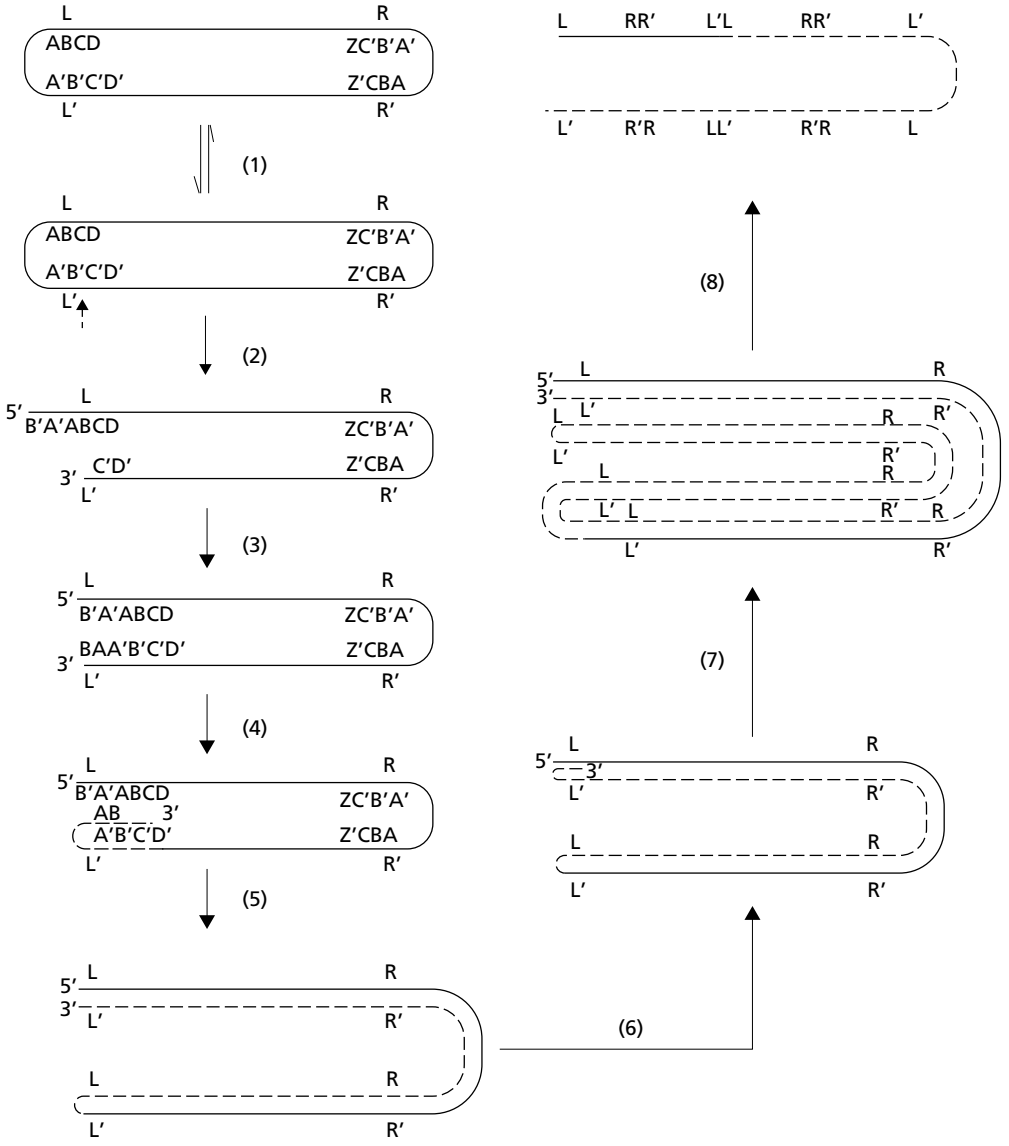

Figure 6 *The replication of* Orthopoxvirus *DNA. The viral genome is indicated at the top left with 'L' and 'R' orientation of the molecule as indicated. Replication begins with introduction of a nick near one or both termini of the genome (indicated schematically by arrow between B′ and C′) followed by strand extension. Parental DNA is indicated by solid lines, newly synthesized DNA by dashed lines. Following strand extension, self-primed replication creates a new hairpin, replication of the genome, and creation of a concatemeric genomic dimer. See text for details. (From Moyer and Graves 1981)*

E9L,VACWR 065) (McDonald and Traktman 1994), a uracil DNA glycosylase (ORF D4R, VACWR 109) (Stuart et al. 1993; Upton et al. 1993; Millns et al. 1994), a serine/threonine protein kinase (ORF B1R, VACWR 183) (Banham and Smith 1992), an NTPase (ORF D5R, VACWR 110), (Evans and Traktman 1992; Evans et al. 1995), and ORF A20, VACWR 141, a processivity factor (Ishii and Moss 2001a); (Punjabi et al. 2001) which acts in concert with the E9L DNA polymerase. The single known exception to the universal conservation of these proteins is B1R, which is absent from MCV. Inactivation of any of these proteins leads to a DNA negative phenotype and is lethal to the virus.

The DNA polymerase is a 110 kDa protein with a 3′-exonuclease proofreading activity and is a target of several antiviral drugs such as aphidicolin (DeFilippes 1984), cytosine arabinoside, and phosphonoacetic acid (Traktman et al. 1989; Taddie and Traktman 1993). Recently, A20R has been shown to function as a processivity factor for the DNA polymerase and to interact with the D4R and D5R proteins as well (McCraith et al. 2000; Ishii and Moss 2001a; Klemperer et al. 2001; Punjabi et al. 2001; Ishii and Moss 2002). Temperature-sensitive mutants in either protein lead to rapid inhibition of DNA synthesis (Sridhar and Condit 1983; Punjabi et al. 2001).

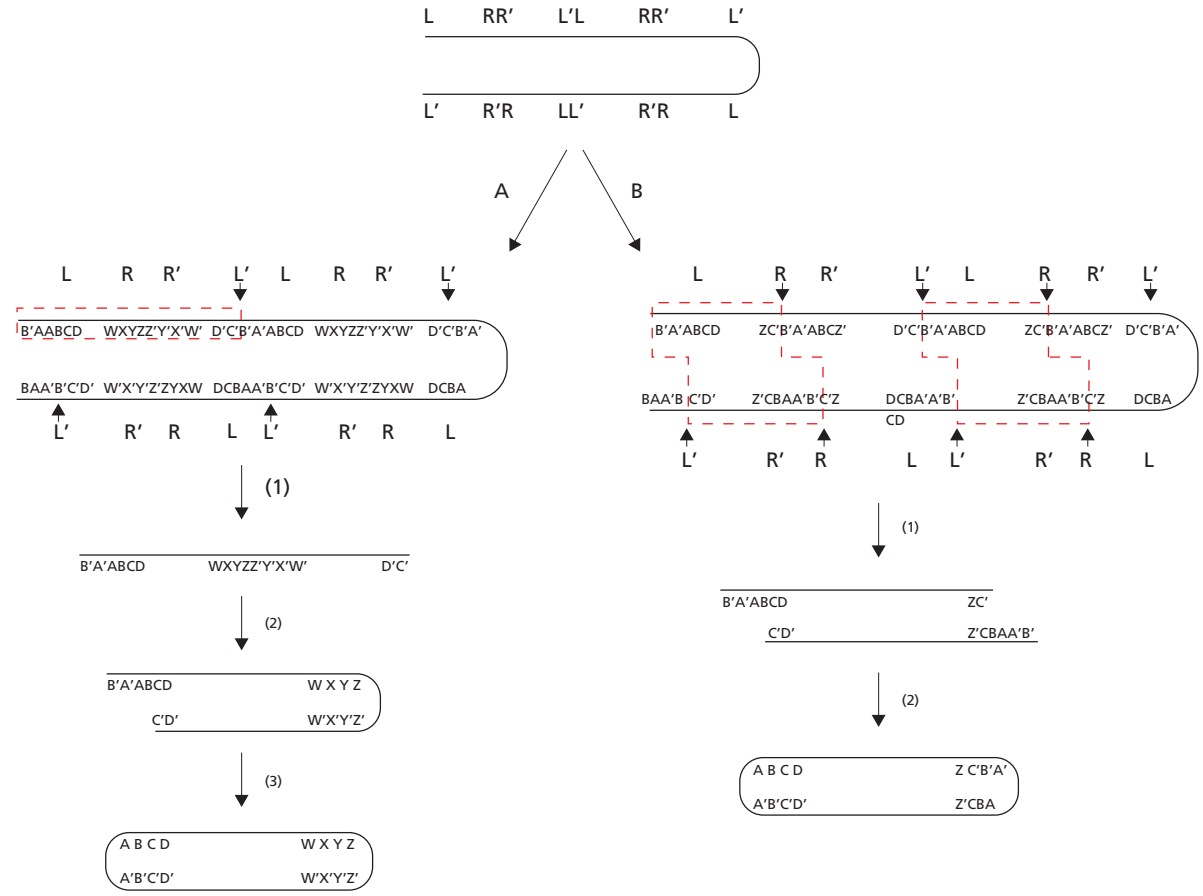

Figure 7 *Generation of mature poxvirus virion DNA from replicative concatamers. Generation of monomeric genomic DNA is initiated by single-stranded nicking (B′C′) as indicated by the arrow. Genomic DNA can be derived either in a* cis *(left) or* trans *(right) fashion from the concatemer as indicated by the red boxes. The designations L and R serve to orient the left and right termini of the molecules and where L′ and R′ are sequences complementary to those of L and R, respectively. (From Moyer and Graves 1981)*

The uracil DNA glycosylase is a small 25 kDa protein and in most systems typically functions as a repair enzyme, excising from DNA uracil residues which arise from misincorporation of dUMP by the DNA polymerase or by deamination of cytosine. The ultimate result of this activity is to leave a gap that is filled by the DNA polymerase. Therefore, the discovery that this protein is absolutely required for the replication of poxvirus DNA (Stuart et al. 1993; Millns et al. 1994; Ellison et al. 1996) was somewhat surprising. Recently, the conserved reactive site of the glycosylase was mutated, eliminating the enzymatic activity which excises uracil from DNA, yet the protein could still function in the process of DNA replication (De Silva and Moss, 2003). Therefore, while the D4R protein is required for DNA replication, the uracil DNA glycosylase activity per se is not. Interestingly, virus containing the enzymatically inactive glycosylase gene, while normal for DNA replication, is attenuated when the virus was used to infect mice.

The NTPase is a 785 amino acid protein which exhibits DNA-independent hydrolysis of both ribo- and deoxy-NTPs. Temperature-sensitive mutants in the protein exhibit a 'fast stop' inhibition of DNA synthesis at nonpermissive temperatures (Evans et al. 1995) as well as being impaired in homologous recombination (Evans and Traktman 1992). As might be expected at nonpermissive temperatures, intermediate and late gene expression is severely affected (Diaz-Guerra and Esteban 1993).

The BIR serine/threonine protein kinase is a 34 kDa protein. When a virus containing thermosensitive mutations in this gene are incubated at nonpermissive temperatures, DNA synthesis ceases. This protein is expressed early in infection but is packaged into mature virions (Banham and Smith 1992; Lin et al. 1992; Rempel and Traktman 1992). One substrate of the B1R kinase is the *H5R* gene (Beaud et al. 1995), which also forms a complex with B1R (McCraith et al. 2000). However, the role of the H5R phosphoprotein is complex and appears to be involved both in the transcription of late viral genes (Kovacs and Moss 1996) as well as morphogenesis (Demasi and Traktman 2000).

The *A50R/VACV-WR_176* gene, encodes a 63 kDa DNA ligase (Kerr and Smith 1991; Parks et al. 1994,

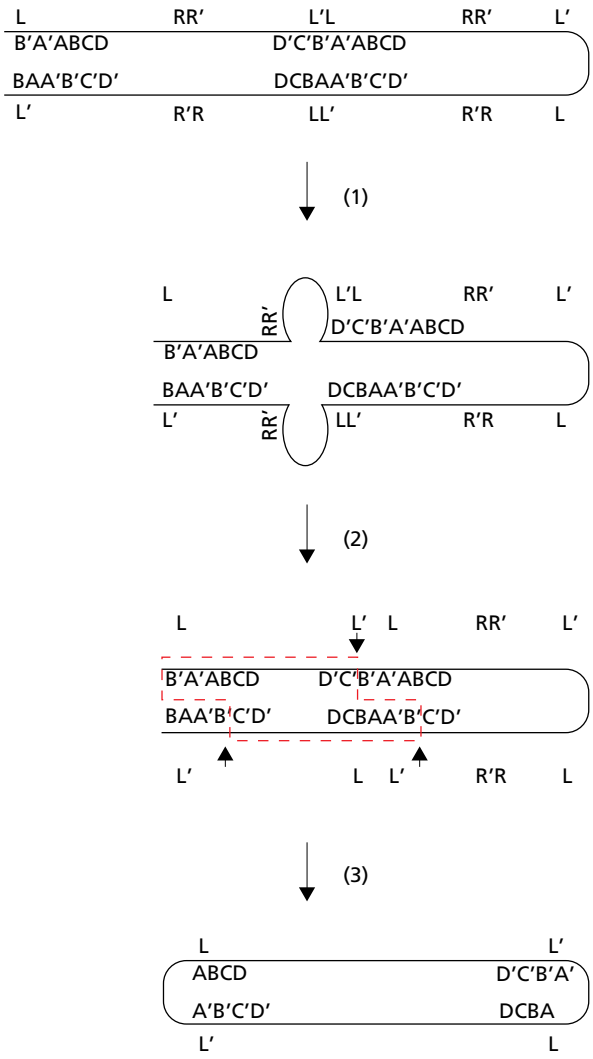

Figure 8 *Mechanism for expansion and contraction of TIR regions. A replicative, concatemeric DNA intermediate is shown. Deletion from within the array (step 1) followed by molecular excision is governed by the hypothetical concatemeric resolution signal (B′C′) and indicated by the red box. Limits of the deletion are theoretical determined by viability of the deleted genomic molecule. In the example shown, the TIR is expanded by addition of sequences from the left end of wild-type molecule. (From Moyer and Graves 1981)*

1998). Disruptions of the DNA ligase lead to a cell-line-dependent phenotype. In some cell lines, there is poor growth of virus accompanied by a two- to tenfold decrease in DNA synthesis. In other cell lines, there is little if any effect (Parks et al. 1998). This difference may be due to the levels of available host DNA ligase present in the cytoplasm.

A number of the other conserved proteins are assumed to be required for later steps in the replicative process but direct genetic evidence is lacking for most of them. Mutations in these genes would be predicted to not lead to defects in DNA synthesis per se, but rather to defects in maturation of the newly synthesized DNA which in turn leads to inhibition of progeny virus formation. The *A22R/VACV-WR_142* gene encodes a resolvase and has been shown by the use of conditional, inducible mutants to be required for resolution of concatemeric DNA into monomers (Garcia et al. 2000; Garcia and Moss 2001).

The function of two of these conserved genes is not yet clear. The *H6R/VACV-WR_104* gene encodes a 314 amino acid type 1 topoisomerase (Shuman and Moss 1987; Shuman et al. 1989), which is the smallest known topoisomerase. Attempts to isolate mutant virus deleted for this gene were unsuccessful, suggesting the gene is essential for growth (Shuman et al. 1989). Furthermore, no conditional lethal mutant has yet been isolated so the precise function of the topoisomerase in virus growth remains to be elucidated. The 34 kDa *I3L/VACV-WR_072* gene encodes a single-stranded DNA-binding protein (Rochester and Traktman 1998; Tseng et al. 1999). The I3L protein has been found localized to virosomes or factories during DNA replication (Rochester and Traktman 1998). When DNA synthesis is blocked, the protein is found in distinct foci within the cytoplasm (Domi and Beaud 2000). It has been suggested that these cytoplasmic spots are specialized sites where DNA release from incoming virus cores accumulates (Welsch et al. 2003). Elucidation of the precise role of both the *H6R* and *I3L* genes in the replicative process awaits isolation of conditional lethal mutants.

Recombination is an essential feature of DNA replication. Indeed, recombination between genetically marked viruses or transfected plasmids and viral DNA is rampant, which in practice facilitates generation of genetically engineered viruses. The processes of recombination and replication are linked and mutations which impair recombination are also impaired in DNA replication (Merchlinsky 1989; Colinas et al. 1990; Evans and Traktman 1992).

Finally, there are a number of poxvirus genes devoted to the purpose of maintaining intracellular nucleotide pools which serve as substrates for DNA synthesis. These enzymes, many of which are not absolutely essential for growth include:

- the 177 amino acid *J2R/VACV-WR_094*) which encodes a thymidine kinase (Hruby and Ball 1982) active as a tetramer (Black and Hruby 1990)
- the *A48R/VACV-WR_178* protein, a 204 amino acid thymidylate kinase (Hughes et al. 1991)
- a 147 amino acid dUTPase, the product of gene *F2L/VACV-WR_041* (Broyles 1993)
- the heterodimeric ribonucleotide reductase comprising the 771 amino acid *I4L/VACV-WR_073* and the 319 amino acid *F4L/VACV-WR_043* subunits (Slabaugh and Mathews 1986; Slabaugh et al. 1988; Tengelsen et al. 1988; Rajagopal et al. 1995).

Table 4 *Poxvirus genes involved in DNA replication*

VACCOP ORF	VACWR ORF	Size (aa)	Description
Orthopoxvirus proteins required for DNA synthesis			
A20R	141	49.1 kDa (426)	DNA polymerase processivity factor
B1R	183	34 kDa (300)	Serine/Threonine phosphokinase
D4R	109	25 kDa (218)	Uracil DNA glycosylase
D5R	110	90 kDa (785)	Nucleoside triphosphatase
E9L	065	116 kDa (1 006)	DNA polymerase
Orthopoxvirus proteins required for other aspects of DNA replication			
A22R	142	22 kDa (187)	Holliday junction resolvase
H6R	104	36 kDa (314)	DNA topisomerase
I3L	072	24 kDa (269)	ssDNA-binding protein
A50R	176	63 kDa (552)	DNA ligase
D5R	110	90 kDa (785)	Nucleotide phosphatase

Poxvirus genes involved in DNA replication are divided into two groups: viral genes directly involved in the synthesis of DNA for which genetic evidence (*ts* mutants exist) (top) or those genes involved in replication and/or post-replicative events for which genetic evidence needed to conclude these genes are essential for replication is generally lacking.

POXVIRUS TRANSCRIPTION AND REGULATION OF VIRAL GENE EXPRESSION

Overview

Gene expression during poxvirus infection occurs in a tightly regulated temporal cascade featuring sequential synthesis of early, intermediate, and late gene (the latter two are termed postreplicative) products. The regulation of poxviral gene expression is most dramatically and elegantly revealed in a simple protein metabolic labeling experiment in which infected cells are pulse labeled with a radioactive amino acid at varying times after infection and the proteins synthesized during each pulse are visualized by gel electrophoresis and autoradiography (Figure 9). Typically this experiment reveals a rapid shutoff of host protein synthesis within the first 4 hours of infection, a burst of early protein synthesis which peaks at 2 hours post-infection and disappears by 6 hours post-infection, synthesis of intermediate proteins which peaks by 4 hours post-infection and decays thereafter, followed by synthesis of late proteins which peaks by 6 hours post-infection and persists through at least 16 hours of infection. Importantly, viral DNA replication initiates with the peak of early protein synthesis, and is a prerequisite for intermediate and late protein synthesis (Pennington 1974).

Mechanistically, gene expression is regulated at the level of transcription (reviewed by Condit and Niles 2002; Broyles 2003). The early, intermediate, and late gene classes are distinguished by class-specific transcriptional promoters and cognate *trans*-acting factors. In general, each gene class encodes factors required for transcription of the succeeding gene class, resulting in the observed temporal cascade of gene expression (Kovacs et al. 1994). Thus, early mRNAs, transcribed by enzymes packaged within infecting virions, encode intermediate gene transcription factors; intermediate genes encode late gene transcription factors; late genes encode early gene transcription factors which are packaged into virions together with RNA polymerase and other RNA metabolism enzymes for the next round of infection. As noted above, both intermediate and late transcription are coupled to DNA replication, that is, inhibitors of DNA replication prevent synthesis of intermediate and late RNAs (Oda and Joklik 1967; Vos and Stunnenberg 1988; Baldick and Moss 1993). Transcription of intermediate and late genes also requires the synthesis of new RNA polymerase, which is synthesized early during infection (Hooda-Dhingra et al. 1989).

All poxvirus genes apparently contain their own promoters; polycistronic mRNAs with internal ribosome entry sites have not been described, and poxviral mRNAs are not spliced. Regardless of gene class, poxvirus promoters are relatively simple and are contained entirely within approximately 30 nt upstream from the transcription initiation site (Davison and Moss 1989a, 1989b; Baldick et al. 1992). Importantly, several genes have been described which contain compound promoters and are therefore expressed at multiple stages of infection (Wittek et al. 1980; Broyles and Pennington 1990).

As stated previously, because poxviruses replicate in the cytoplasm of infected cells, the virus encodes virtually all of the enzymes required for regulated synthesis and modification of mRNAs suitable for translation in a eukaryotic environment. Thus at least 23 virus genes

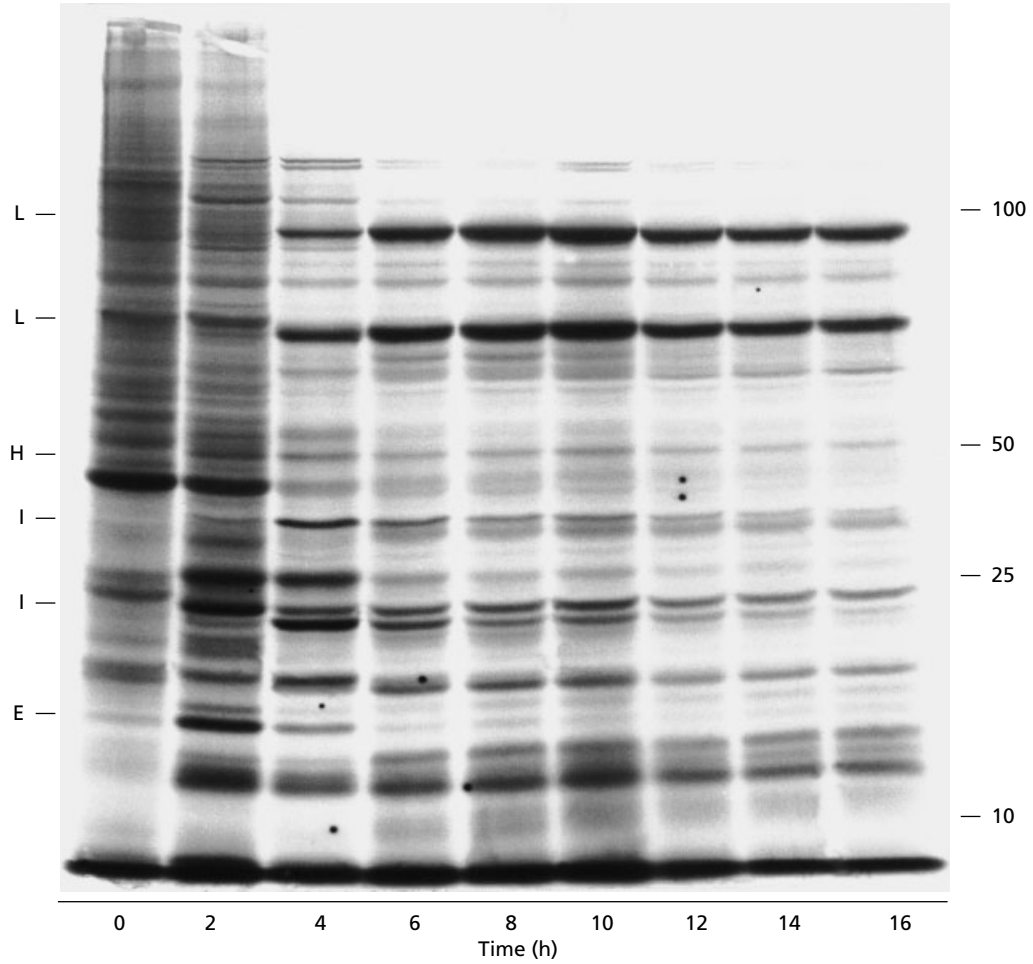

Figure 9 *Kinetics of gene expression in vaccinia virus-infected cells. Cells were infected with vaccinia virus at a multiplicity of infection of 10 plaque-forming units/cell, and metabolically pulse labeled with [^{35}S]methionine for 15 minutes at 2-hour intervals following infection. Proteins were separated by SDS-PAGE. An autoradiograph of the dried gel is shown. Each lane on the autoradiogram reveals the proteins that were being synthesized at the time after infection that the radiolabel was present, indicated under each lane. Molecular mass markers are shown at the right of the autoradiogram. At the left is indicated the migration of selected late (L), intermediate (I), and early (E) viral proteins, and a host (H) protein.*

have been described which play a direct role in viral mRNA synthesis and modification (Table 2). Interestingly, viral transcription may not be completely independent of the host; a limited number of host proteins have also been identified which may play a role in virus transcription (Rosales et al. 1994b; Broyles et al. 1999; Wright et al. 2001).

In the paragraphs below, we first describe the enzymes and reactions common to synthesis and modification of all classes of poxviral mRNA, and then focus in detail on differences in the expression of each gene class.

RNA polymerase

The virus-encoded RNA polymerase is a multisubunit enzyme which exists in two forms, one specific for early genes and one specific for intermediate and late genes (Table 2). The two forms of the enzyme contain eight subunits in common; the only difference between the two forms of the enzyme is that the early gene-specific enzyme contains one additional subunit, RAP94 (H4L/VACV-WR_102) (Nevins and Joklik 1977; Baroudy and Moss 1980; Ahn et al. 1994). Among the eight common subunits, the two largest, RPO147 (J6R/VACV-WR_098) and RPO132 (A24R/VACV-WR_144), share extensive homology with the largest subunits of both eukaryotic and prokaryotic multisubunit RNA polymerases (Broyles and Moss 1986; Patel and Pickup 1989; Amegadzie et al. 1991b). Another subunit, RPO30 (E4L/VACV-WR_060), also shows homology with the eukaryotic transcription elongation factor TFIIS (Ahn et al. 1990a). Interestingly, this subunit also serves as an intermediate gene transcription factor (Rosales et al. 1994a). The smallest vaccinia RNA polymerase subunit, RPO7 (G5.5R/VACV-WR_083), shows homology to the smallest subunit of eukaryotic RNA polymerase II

(Amegadzie et al. 1992). Neither of the remaining four common subunits nor RAP94 show significant homology to other eukaryotic or prokaryotic proteins.

Both forms of the viral RNA polymerase, RAP94+ and RAP94−, are found in virions as well as in the cytoplasm of infected cells. The activities of these enzymes are mutually exclusive, that is, the RAP94+ enzyme transcribes only early viral genes and not postreplicative genes, whereas the RAP94− enzyme transcribes only postreplicative genes and not early genes (Wright and Coroneos 1995). Importantly, this means that the RNA polymerase which transcribes either early or postreplicative genes retains a memory of the class of promoter at which transcription was initiated. This impacts significantly on termination of transcription, which occurs differently on early and postreplicative genes, as described in more detail below.

mRNA capping

All classes of poxviral mRNAs contain a 5′ cap-1 structure, in which the first transcribed nucleotide is modified by addition of a 7-methylguanine in a 5′– 5′ triphosphate linkage, and is also methylated on the 2′-hydroxyl group of the ribose moiety (Wei and Moss 1975). The entire process comprises four reactions carried out by two virus-coded enzymes (Table 4). The first three reactions are carried out by the mRNA capping enzyme, a heterodimer composed of the 97 kDa *D1R* gene product (*D1R/VACV-WR_106*) and the 33 kDa *D12L* gene product (*D12L/VACV-WR_117*) (Martin et al. 1975; Morgan et al. 1984; Niles et al. 1989). The capping enzyme first removes the gamma phosphate from a nascent, triphosphorylated mRNA, then adds a GMP in a 5′–5′ linkage, and finally methylates the added guanine in the 7 position to yield a cap-0 structure. The triphosphatase and guanylyltransferase active sites are located on the large D1R subunit of the enzyme, whereas the guanine methyltransferase active site is located on the small, D12L subunit of the enzyme (Shuman and Morham 1990; Higman et al. 1994; Mao and Shuman 1994). Methylation of the ribose on the first transcribed nucleotide requires the cap-0 RNA (guanylylated and methylated on the cap guanine base, but not ribose methylated) as a substrate, and is catalyzed by a monomeric (nucleoside-2′-*O*-)-methyltransferase, the 39 kDa product of the *J3R* gene (*J3R/VACV-WR_095*), to yield a cap-1 structure (Barbosa and Moss 1978a; Barbosa and Moss 1978b; Schnierle et al. 1992). Interestingly, both the capping enzyme and the (nucleoside-2′-*O*-)-methyltransferase are multifunctional enzymes. The D1R/D12L capping enzyme also participates in early gene transcription termination, intermediate gene transcription initiation, and may also play a role in telomere resolution during processing of replicated viral DNA concatemers to monomeric genomes (Shuman et al. 1987; Carpenter and DeLange 1991; Vos et al. 1991; Hassett et al. 1997). In addition to its role in mRNA capping, the J3R (nucleoside-2′-*O*-)-methyltransferase serves as a stimulatory subunit for the viral poly(A) polymerase, and also as a transcription elongation factor for postreplicative genes (Gershon et al. 1991; Latner et al. 2002). All three genes involved in the capping reactions are essential virus genes; however, the phenotypes of mutants in these genes do not obviously relate to the capping reaction per se. Specifically, temperature-sensitive mutants in either of the mRNA capping enzyme subunit genes (*D1R* or *D12L*) are unaffected in viral gene expression but defective in telomere resolution and morphogenesis (Carpenter and DeLange 1991; Hassett et al. 1997). Formation of the cap-0 structure is presumed to be essential for mRNA stability and translation during virus infection, but this has never been demonstrated in poxviruses directly. The J3R protein is essential only for its transcription elongation function; selective inactivation of the (nucleoside-2′-*O*-)-methyltransferase activity of the J3R protein to produce a virus which synthesizes only cap-0 mRNAs has no apparent effect on virus growth (Latner et al. 2002).

Polyadenylation

All classes of poxviral mRNAs are polyadenylated by a virus-coded heterodimeric enzyme consisting of the 55 kDa *E1L* gene product (*E1L/VACV-WR_057*) and the 39 kDa *J3R* gene product (*J3R/VACV-WR_095*) (reviewed by Gershon 1998) (Table 2). The catalytic site for polyadenylation resides in the E1L protein; however, the E1L protein on its own can processively add only approximately 35 adenylate residues to an RNA 3′ end (Gershon and Moss 1992). In the presence of the J3R subunit, full length poly(A) tails averaging 100 nt in length are synthesized; thus the J3R protein is described as the stimulatory or processivity subunit of the poly(A) polymerase (Gershon and Moss 1993a). The poly(A) polymerase is relatively promiscuous and will polyadenylate virtually any available RNA 3′ end providing it contains uridylate residues positioned at specific sites near the RNA 3′ end (Gershon and Moss 1993b). The poly(A) stimulatory and ribose methyltransferase activities of the J3R protein are independent of one another, and occupy opposite faces of an oblate sphere (Hodel et al. 1996; Gershon et al. 1998).

Early gene transcription

Early vaccinia genes are transcribed in the cell cytoplasm from partially uncoated virion cores. Early transcripts are detectable within 20 minutes following infection, they reach a peak of synthesis by 100 minutes following infection, and decline thereafter with a half-life of approximately 30 minutes (Baldick and

Moss 1993). Early gene products number at least 50, representing at least 25 percent of the coding capacity of the vaccinia genome, and include enzymes required for DNA replication, new viral RNA polymerase and capping enzyme, host defense functions, plus intermediate gene-specific transcription factors (viral intermediate transcription factors (VITF)) required for transcription from intermediate transcriptional promoters.

Mutational analysis demonstrates that poxvirus early transcriptional promoters contain an A/T rich critical core region located between −13 and −27 relative to the RNA start site (Davison and Moss 1989a). Transcription usually starts with a purine residue, but otherwise the residues between −1 and −12, described as a 'spacer' region, are insensitive to substitution mutation. Early transcription start sites are usually located approximately 5–30 nt upstream of the ATG translation initiation codon for a given gene; however, early mRNA 5′ untranslated regions of up to 600 nt in length have been reported (Lee-Chen et al. 1988; Pacha et al. 1990; Meis and Condit 1991).

The viral early transcription factor (VETF) is a heterodimeric promoter-binding ATPase composed of the 82 kDa *A7L* gene product (*A7L/VACV-WR_126*) and the 74 kDa *D6R* gene product (*D6R/VACV-WR_111*) (Broyles and Fesler 1990; Gershon and Moss 1990) (Table 2). VETF is the only member of the poxvirus transcription factors that has been shown to bind directly and specifically to its cognate promoter. VETF makes sequence-specific contacts with the promoter core region, and also makes DNA contacts in a nonsequence-specific fashion directly downstream of the initiator (Broyles et al. 1991; Cassetti and Moss 1996). Upon binding to the promoter, VETF recruits RNA polymerase to the promoter and then dissociates, hydrolyzing ATP in the process (Broyles 1991). As noted above, the RAP94 subunit of the RNA polymerase is also required for initiation at early promoters.

Termination of early gene transcription is an energy-dependent, sequence-specific event requiring virus-coded *trans*-acting factors (reviewed by Condit and Niles 2002). The sequence which triggers early gene transcription termination is UUUUUNU, occurring in the nascent RNA (Yuen and Moss 1987; Shuman and Moss 1988). Termination occurs 30–50 nt downstream from this sequence. Three viral proteins are required for early termination, the capping enzyme (called the viral termination factor (VTF) in the context of termination), the RAP94 early RNA polymerase subunit, and a 72 kDa DNA-dependent ATPase, called NPH I, the product of gene *D11L* (*D11L/VACV-WR_116*) (Shuman et al. 1987; Christen et al. 1998; Deng and Shuman 1998; Mohamed and Niles 2001) (Table 2). NPH I provides the energy required for termination, and directly contacts RAP94 (Mohamed and Niles 2000). The activity of the capping enzyme in termination is independent of its mRNA capping activity (Luo et al. 1995; Yu and Shuman 1996). Otherwise, the precise roles of these three proteins in early gene termination and the mechanism of sequence recognition remain to be determined.

Intermediate gene transcription

Intermediate transcription is triggered by the synthesis of intermediate gene transcription factors coupled with the initiation of viral DNA replication (Vos and Stunnenberg 1988). Intermediate mRNAs are detectable by 100 minutes post-infection and peak by 120 minutes post-infection, declining thereafter with a 30 minute half-life (Baldick and Moss 1993).

The identification of intermediate genes from among postreplicative genes is not straightforward and requires one or more specific in vivo or in vitro tests. For example, individual candidate genes may be tested for expression in vivo after infection with a temperature-sensitive mutant virus which is specifically defective in a late transcription factor (Carpenter and DeLange 1992). Only seven intermediate genes have so far been positively identified, and these encode a variety of functions including some host defense functions, DNA and RNA metabolism functions, and, importantly, viral late transcription factors (VLTF) which are required for recognition of late viral transcriptional promoters (Keck et al. 1990; Zhang et al. 1992; Xiang et al. 1998). Many of the postreplicative genes which are now classified as late will probably ultimately prove to be intermediate when subjected to appropriate tests for expression.

Intermediate gene promoters consist of two critical elements, an initiator region, TAAA, located at −1 to +3 relative to the RNA start site, and an A/T rich core element located at −13 to −26 (Baldick et al. 1992). The spacer region from −2 to −12 is insensitive to substitution mutation. The TAAA initiator motif may be located directly upstream from or even incorporate the translation initiating ATG. When initiating at intermediate promoters, RNA polymerase apparently retranscribes the AAA sequence of the initiator multiple times, slipping upstream between transcription events without releasing the nascent RNA, resulting in synthesis of a 30 nt nontemplated 5′ 'poly(A) head' (Bertholet et al. 1987; Schwer et al. 1987; Baldick and Moss 1993). (Because of this slippage reaction, the +1 nucleotide cannot be unambiguously assigned; it is arbitrarily and logically designated as the upstream A in the TAAA initiator motif.) No function for the poly(A) head has been demonstrated; however, it would provide a 5′ untranslated region for mRNAs transcribed from genes in which the promoter is directly abutted to the translation initiation ATG.

Four factors have been identified which are required for maximal expression of intermediate genes in vitro (Table 2). These include the heterodimeric D1R/D12L mRNA capping enzyme, and three intermediate

transcription factors, VITF 1, VITF 2, and VITF 3 (Vos et al. 1991; Rosales et al. 1994a, 1994b; Sanz and Moss 1999). (Earlier, independent experiments identified the mRNA capping enzyme and one additional intermediate gene transcription factor, VITF-B; the relationship between VITF-B and VITF 1–3 has not been determined; Vos et al. 1991.) VITF 1 and 3 are virus-coded, and VITF 2 is a cellular protein. VITF 1 is identical to the 30 kDa RNA polymerase subunit RPO30, the product of the *E4L* gene (*E4L/VACV-WR_060*). VITF 3 is a heterodimer comprising the 34 kDa *A8R* gene product (*A8R/VACV-WR_127*) and the 45 kDa *A23R* gene product (*A23R/VACV-WR_143*). The cellular protein remains to be identified. The precise mechanism of action of these proteins in intermediate gene transcription remains to be determined. In addition to these four factors, evidence suggests that the cellular transcription factor YY1 may play a role in transcription of some intermediate genes (Broyles et al. 1999; Broyles 2003). Specifically, YY1 is mobilized from the cell nucleus into the cytoplasm following poxvirus infection, and binds in vitro to intermediate promoters containing the sequence TAAATGG.

Termination of intermediate and late gene transcription occurs by a similar mechanism and is fundamentally different from termination of early gene transcription (reviewed by Condit and Niles 2002). During transcription of intermediate genes, the early transcription termination signal, UUUUUNU, is ignored, presumably because the RNA polymerase which transcribes intermediate genes lacks RAP94 (Condit et al. 1996a). Instead, RNA polymerase transcribing intermediate genes apparently terminates inefficiently at multiple sites, such that each intermediate gene is transcribed to yield an extremely 3′-end heterogeneous family of transcripts ranging in size from 1 to 4 kb, regardless of the size of the gene being transcribed (Mahr and Roberts 1984). Genetic and biochemical experiments have identified three virus-coded factors which influence the length of intermediate transcripts, and therefore play a role in intermediate gene transcription elongation or termination (Table 2). Specifically, genetic inactivation of the *A18R* gene (*A18R/VACV-WR_138*) results in the synthesis of longer than normal intermediate mRNAs, while conversely, genetic inactivation of either the *G2R* (*G2R/VACV-WR_080*) or *J3R* (*J3R/VACV-WR_095*) genes results in the synthesis of 3′-truncated mRNAs (Black and Condit 1996; Xiang et al. 1998; Latner et al. 2000). The complementary phenotypes of these mutants is reinforced by the fact that mutations in either *G2R* or *J3R* will suppress mutations in *A18R* (Condit et al. 1996b; Latner et al. 2000). The 56 kDa *A18R* gene product is a DNA-dependent ATPase and a 3′–5′ DNA helicase, and will catalyze release of RNA from a transcription elongation complex in an energy-dependent fashion in vitro (Bayliss and Condit 1995; Simpson and Condit 1995; Lackner and Condit 2000). The A18R protein is therefore likely to be a transcription termination factor, consistent with the phenotype of A18R-deficient mutants in vivo. As described above, the J3R protein also serves as the mRNA cap (nucleoside-2′-*O*-)-methyltransferase, and the poly(A) polymerase stimulatory factor. The transcription elongation activity of J3R is genetically separable from and therefore functionally independent from its other two activities (Latner et al. 2002). The 26 kDa G2R protein has no significant homology to other characterized proteins. In vitro assays for the transcription elongation functions of J3R and G2R have yet to be developed.

Late gene transcription

Late viral mRNAs are detectable by 140 minutes post-infection, and continue to be synthesized throughout infection (Baldick and Moss 1993). Genes currently classified as late genes may comprise as much as 75 percent of the vaccinia genome; however, some of these are likely to be intermediate genes as discussed above. Late mRNAs encode the majority of virus structural and assembly functions and virion enzymes, including the VETF which is packaged into newly assembled virions along with RNA polymerase and RNA modification enzymes for use in the next round of infection.

Late transcriptional promoters are very similar to intermediate transcriptional promoters. Late promoters consist of an AT-rich core located at −11 to −16 relative to the RNA start site, and a TAAAT initiator motif located between −1 and +4 (Davison and Moss 1989b; Broyles 2003). The similarity between late and intermediate promoters is illustrated by the observation that mutation of an ACA trinucleotide to CCC at positions −15 to −17 in the gene *I3L* intermediate promoter changes the promoter to a late promoter (Hirschmann et al. 1990). Like intermediate transcripts, late gene mRNAs contain a 5′ poly(A) head, synthesized via RNA polymerase slippage at the TAAAT initiator motif (Patel and Pickup 1987; Ahn and Moss 1989).

Genetic and biochemical experiments have identified at least five VLTFs which are required for maximal transcription from late promoters (Table 2). VLTF 1–4 are virus-coded factors. VLTF 1–3, identified through genetic experiments, are the products of the intermediate genes *G8R* (*G8R/VACV-WR_086*, 30 kDa), *A1L* (*A1L/VACV-WR_119*, 17 kDa), and *A2L* (*A2L/VACV-WR_120*, 26 kDa), respectively. VLTF 4 is the product of gene *H5R* (*H5R/VACV-WR_103*), a 22 kD early phosphoprotein which stimulates late transcription in vitro. A fifth cellular factor, VLTF-X, which stimulates transcription from late vaccinia promoters in vitro, has recently been identified as consisting of the heterogeneous nuclear ribonucleoproteins A2/B1 and RBM3 (Wright et al. 2001). The specific roles of each of the late transcription factors has yet to be determined.

Elongation and termination of late mRNAs appears to occur by mechanisms identical to intermediate mRNAs. Specifically, late mRNAs are 3′-end heterogeneous, and their length is regulated by the products of genes *A18R*, *G2R*, and *J3R* (Condit and Niles 2002).

Interestingly, a few late poxvirus mRNAs possess homogeneous 3′ ends, and in the case of the cowpox virus *ATI* gene, it has been determined that the homogeneous 3′ end is generated by a sequence-specific, post-transcriptional endoribonuclease cleavage reaction catalyzed by a virus-induced enzyme (Howard et al. 1999). Whether this cleavage reaction is limited to just a few mRNAs or plays a broader role in infection remains to be determined.

Additional regulation: host shutoff and RNA turnover

Sequential synthesis of transcription initiation factors accounts only for the onset of synthesis of successive classes of poxvirus gene products; additional mechanisms must regulate the shutoff of host gene expression and the decay in expression of early and intermediate genes as infection progresses. One factor which clearly plays a role in the decay of cellular and viral gene expression is a global reduction in stability of mRNA induced by poxvirus infection. For example, β-actin mRNA, which normally has a half-life of 10 hours in uninfected cells, is rapidly degraded upon vaccinia infection (Rice and Roberts 1983). In general, late viral mRNAs have a half-life of less than 60 minutes (Oda and Joklik 1967). In addition, host-gene expression may be altered by virus infection both by inhibition of cellular RNA polymerase and by inhibition of translation of cellular mRNA (Puckett and Moss 1983; Cacoullos and Bablanian 1993) .

POXVIRUS MORPHOGENESIS

Overview

Electron microscopic examination of poxvirus-infected cells reveals discrete stages of virus morphogenesis with characteristic intermediate structures associated with each stage (Dales and Pogo 1981; Griffiths et al. 2001a, 2001b; Risco et al. 2002; Sodeik and Krijnse-Locker 2002). The earliest evidence of poxvirus infection is the appearance in the cytoplasm of discrete granular foci which are largely devoid of normal cellular organelles. These foci, called ‘viroplasm’ or ‘viral factories,’ contain replicating viral DNA and are often surrounded by cellular membranes derived from the endoplasmic reticulum (Tolonen et al. 2001). As the infection progresses, viral factories increase in size. The first evidence of virion morphogenesis is the appearance within the viroplasm of rigid, crescent-shaped membrane structures (cupules in three dimensions) which are precursors to the IMV membrane (Figure 10). The origin of these viral membranes is discussed in more detail below. Crescents evolve into circles (spheres in three dimensions), called immature virions (IV), which enclose relatively dense viroplasm (Figure 10). Some IV contain internal ‘nucleoids,’ which are unbounded, extremely electron-dense, DNA-containing structures presumed to be precursors to the virion core (Figure 10). Formation of these nucleoid-containing IV (IVN) is associated with viral DNA packaging, described in more detail below. IVN then mature to IMV containing the classical biconcave core, core envelope, lateral bodies, and outer membrane (Figure 1). Maturation of IV to IMV is essentially a metamorphosis which is presumed to take place via rearrangement of the contents of IVN; while structures which are thought to be intermediates in the IVN to IMV transition have been observed, they are

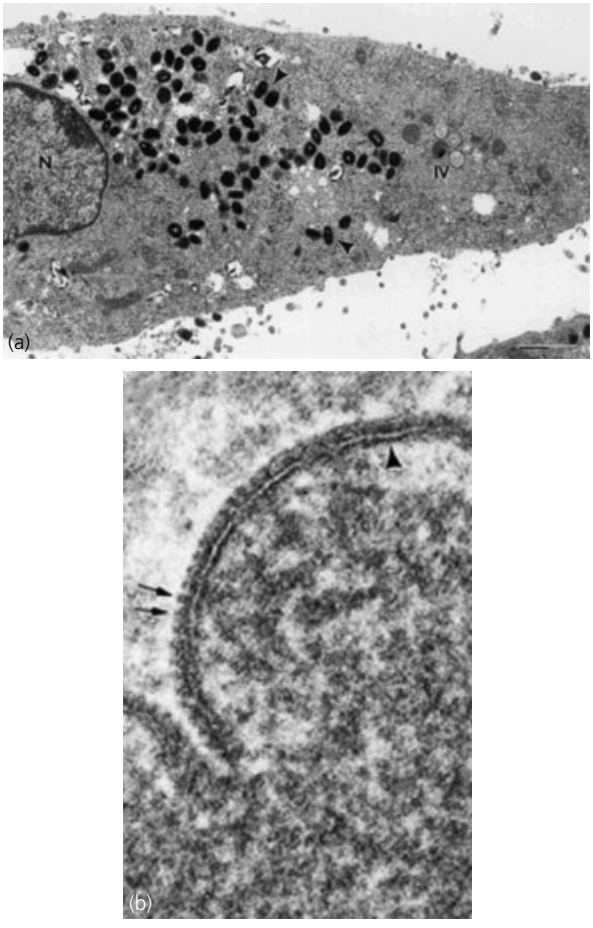

Figure 10 *Electron microscopy of vaccinia virus-infected cells.* **(a)** *Low-magnification field of infected HeLa cells 24 hours post-infection, showing the characteristic accumulation of spherical IV and IVN (marked IV), and dense brick-shaped mature viruses (arrowheads).* **(b)** *High-magnification field showing viral crescents. relatively rare and therefore the process of IMV maturation is probably rapid (Figure 11). Maturation from IVN to IMV is accompanied by proteolysis of several major virion structural proteins; mutation of one of the viral proteases involved in virion protein cleavage interrupts morphogenesis at the IVN to IMV transition (Ericsson et al. 1995; Byrd et al. 2002). Maturation from IVN to IMV is also accompanied by microtubule-mediated migration of the particles from viroplasm toward the periphery of the cell (Sanderson et al. 2000). More than 90 percent of virus does not mature past the IMV stage; a small percentage matures further to eventually be exported from the cell as EEV (Boulter and Appleyard 1973). As described earlier, EEV formation involves first the formation of IEV. IEV consists of IMV surrounded by two additional membranes, acquired via wrapping of IMV in trans-Golgi-network-derived cisternae which have been modified by the incorporation of specific virus proteins (Figure 11) (Schmelz et al. 1994). IEV are mobilized to the undersurface of the plasma membrane on microtubules, where the outermost IEV membrane fuses with the plasma membrane to form CEV (Blasco and Moss 1992; Hollinshead et al. 2001). CEV thus consists of IMV wrapped in one additional membrane, and remains attached to the external surface of the plasma membrane. Actin filament bundles then form beneath CEV pushing outward, resulting eventually in the formation of long, specialized actin-containing microvilli, each of which contains a single

CEV perched at the tip (Stokes 1976; Cudmore et al. 1996). CEV is eventually released from the surface of the cell to become EEV, which, like CEV, consists of IMV surrounded by one additional membrane. Both CEV and EEV mediate short-range and long-range cell-to-cell spread of virus, respectively (Blasco and Moss 1992; Law et al. 2002).

Some poxviruses, including certain strains of cowpox, ectromelia, raccoonpox, fowlpox, and canarypox, also produce an occluded form of virus. These viruses encode an A-type inclusion protein which is produced in large amounts late in infection and which condenses into large, electron dense aggregates in the cell cytoplasm (McKelvey et al. 2002). A-type inclusions are embedded with numerous IMV (Figure 12). While no function for A-type inclusions has been proven, it seems reasonable to assume that they would provide increased environmental stability for the embedded IMV.

Over the past decade, information regarding the contribution of individual virus genes to virus morphogenesis has been gathered by studying virus assembly following infection with mutants in at least 32 different virion proteins. The mutants which have been characterized can be roughly staged into six categories corresponding to the major intermediates in virus assembly (one recent representative reference is provided for each class):

- mutants defective in viral membrane synthesis which accumulate viroplasm devoid of crescents (Demasi and Traktman 2000)
- mutants defective in IV synthesis which accumulate viroplasm containing crescent membranes but no complete IV (Chiu and Chang 2002)

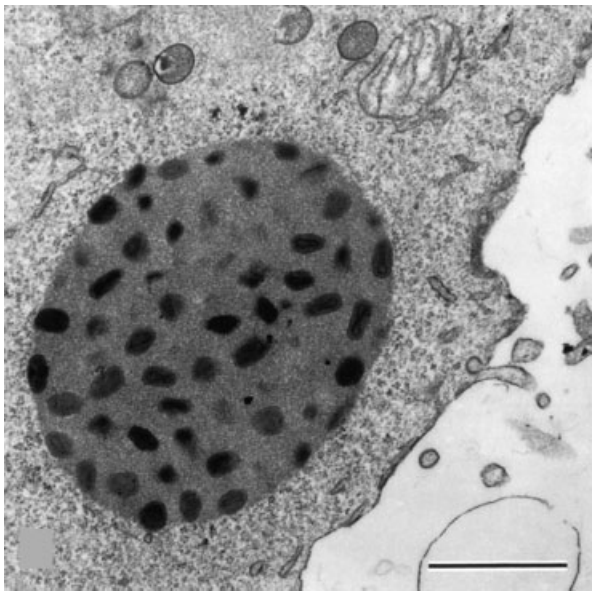

Figure 12 *A-type inclusions in cells infected with cowpox virus. The inclusion contains multiple IMV. Note the IV and IVN immature particles above the inclusion. Bar, 1 000 nm. (From McKelvey et al. 2002)*

- mutants defective in IVN synthesis which accumulate viroplasm containing IV (Yeh et al. 2000)
- mutants defective in IMV synthesis which accumulate viroplasm containing IV and IVN but no IMV (Garcia and Moss 2001)
- mutants which accumulate normal looking IMV which are not infectious (Liu et al. 1995)
- mutants defective in EEV synthesis which accumulate IMV (Sanderson et al. 2000).

Mutants in several of these categories accumulate structures which are not normally seen during wild-type virus infections; such structures may be either normal intermediates in virus assembly or dead-end defective products. Logically, mutants in several IMV membrane proteins are defective in crescent or IV formation (Rodriguez et al. 1995, 1998; Wolffe et al. 1996; Traktman et al. 2000), mutants in several core proteins are defective in maturation of IV to IMV (Klemperer et al. 1997; Williams et al. 1999), and mutants in several EEV membrane proteins are defective in maturation of IMV to EEV (Blasco and Moss 1991; Engelstad and Smith 1993; Wolffe et al. 1993). However, it is also true that mutants in several core proteins and enzymes affect viral membrane formation (Wang and Shuman 1995; Demasi and Traktman 2000), and conversely that mutants in some membrane proteins affect the transition from IV to IMV (Ravanello and Hruby 1994). These genetic studies have also revealed that poxviruses encode a complete pathway for disulfide bond formation which is required for formation of at least some of the disulfide bonds critical for virus structure and assembly (Senkevich et al. 2002). Mutation of any of the genes in the pathway interrupts morphogenesis at the IV to IVN stage.

IV and IMV membrane formation

Two distinct models have been proposed to describe the origin and structure of viral crescents and the IMV membrane. One model proposes that the crescent membranes comprise a single lipid bilayer which arises de novo, that is without continuity with any other intracellular membrane structure (Dales and Mosbach 1968; Hollinshead et al. 1999). This de novo model is based on the observation that, using conventional EM techniques, the crescents and the IMV membrane have dimensions consistent with a single lipid bilayer, and that in most standard EM preparations of virus-infected cells, no convincing connection can be observed between the crescents and any other intracellular membrane system. The notion of de novo biogenesis of a lipid bilayer membrane with free ends and two cytoplasmic surfaces is unprecedented in cell biology. An alternative model which is more consistent with established cell biology principles is that the crescents are formed from membrane cisternae derived from the endoplasmic reticulum–Golgi intermediate

compartment (ERGIC), which, through incorporation of viral proteins, collapse into rigid crescents, such that the crescents and IMV membranes actually comprise two tightly apposed lipid bilayers (Sodeik and Krijnse-Locker 2002). This 'double membrane' model is supported by EM images of IV prepared by freeze substitution, and by EM examination of thin cryosections of infected cells, which under some circumstances reveal apparent localized separation of two membranes within a crescent. In addition, cryosections stained with antibodies to both cellular and viral proteins show labeling of ERGIC membranes with viral proteins, and continuity between crescents and cell-derived ERGIC membrane cisternae (Sodeik et al. 1993; Salmons et al. 1997; Rodriguez et al. 1997; Risco et al. 2002). The double-membrane model is further supported by the clear demonstration of a remarkably similar mechanism of virion membrane biogenesis during maturation of another cytoplasmic DNA virus, African swine fever virus (Andres et al. 1998). Interestingly, infection with mutants in either of the poxvirus IMV membrane proteins A17L or A14L results in aberrant or deficient synthesis of crescents, and accumulation of numerous small vesicles containing viral membrane proteins (Rodriguez et al. 1995, 1998; Wolffe et al. 1996; Traktman et al. 2000). It has been proposed that these vesicles may normally be intermediates in crescent formation (Traktman et al. 2000). The vesicles could be shed from the ERGIC, and would normally be short lived. Crescents formed by fusion and collapse of these vesicles would comprise tightly apposed double membranes, but consistent continuity with the intermediate compartment would be rare, thus explaining the apparent de novo evolution of viral membrane crescents. A similar model of viral membrane formation proposes that the IV membrane is formed by the fusion of ERGIC-derived, viral protein-modified tubules (Risco et al. 2002). Phosphorylation may play a critical role in regulating viral membrane formation, since both the A17L and A14L membrane proteins are phosphorylated by the virus-coded F10L kinase, and mutational inactivation of the F10L kinase abrogates crescent formation (Traktman et al. 1995; Betakova et al. 1999; Derrien et al. 1999).

Viral DNA packaging

The mechanism by which viral DNA is packaged into virions is incompletely understood. Viral DNA concatemers are resolved to unit length genomes during infection with virus mutants that are incapable of forming even the earliest crescent membranes; therefore the final stages of viral DNA processing do not seem to be coupled to morphogenesis (Demasi and Traktman 2000). In theory, unit length viral DNA genomes could be incorporated into IV during membrane synthesis and subsequently condense into nucleoids. However, several investigators have observed IV which are incompletely sealed and which possess a chromatin- or nucleoidlike material positioned across a small opening or pore in the IV, sometimes apparently continuous with the internal nucleoid (Figure 11) (Morgan 1976; Ericsson et al. 1995; Risco et al. 2002). These images are interpreted to mean that DNA is specifically packaged late during IV assembly to form IVN. Interestingly, mutation of the viral gene *A32L*, which contains a predicted ATP/GTP-binding site 'P loop' motif, interrupts virus assembly at the IV to IVN transition, resulting in the accumulation of reduced amounts of IVN and large amounts of a novel, electron-dense spherical particle which does not contain DNA (Cassetti et al. 1998). These observations are consistent with a late DNA packaging model and suggest that the *A32L* gene product may mediate DNA packaging.

One group has proposed recently that viral DNA is packaged through an association of DNA with ERGIC and a second infolding of the DNA-membrane complex into the IV membrane during IVN morphogenesis (Griffiths et al. 2001a, 2001b). This model predicts that the core wall is in fact a double membrane similar to the proposed double-membrane structure for the IV and IMV membrane. Further research is required to substantiate this model.

POXVIRUS GENETICS

Overview

Genetic manipulation of poxviruses has had a broad impact on both poxvirology in particular and biomedical science in general. The influence of poxvirus genetics can be broken down into three specific areas:

- construction of virus mutants for use in determining the function of individual poxvirus genes
- use of recombinant poxviruses for protein over-expression
- use of recombinant poxviruses as vaccine vectors.

Genetic manipulation of poxviruses has taken liberal advantage of both classical 'forward' genetic techniques and modern 'reverse' genetic techniques. Classical forward genetics consists of chemical mutagenesis and random isolation of temperature-sensitive, host-range, drug-resistant, and drug-dependent mutants, followed by employment of genetic mapping procedures to determine which genes have been affected. Modern reverse genetics consists of site-specific engineering of the viral genome, from alteration of existing poxvirus genes in situ to introduction of foreign genes and heterologous transcriptional operons into the poxvirus genome.

Regardless of the application, reverse genetic engineering of poxvirus genomes follows the same fundamental 'in vivo recombination' protocol (Nakano et al. 1982). Specifically, if cells are first infected with a poxvirus and then transfected with a DNA molecule

which has homology with the infecting poxvirus genome, the transfecting DNA molecule will undergo homologous recombination with the infecting genome. A simple example of this principle is marker rescue mapping of temperature-sensitive mutants of vaccinia virus (Thompson and Condit 1986). In this example, cells are infected with mutant virus and transfected with candidate DNA molecules derived from wild-type virus. Homologous recombination between the mutant genome and a transfected DNA molecule which contains the wild-type allele of the gene will generate wild-type virus, thus mapping the temperature-sensitive lesion to a specific rescuing DNA fragment. Several variations on the basic in vivo recombination scheme have been derived which improve the efficiency of the procedure and/or enhance selection for recombinant genomes (Chakrabarti et al. 1985; Franke et al. 1985; Fathi et al. 1986; Falkner and Moss 1990; Merchlinsky and Moss 1992; Scheiflinger et al. 1992). In general, poxvirus recombination is efficient and the genome contains numerous nonessential insertion sites and can accommodate large amounts of foreign DNA, so that almost any recombinant that can be imagined can be constructed. Recently, a novel engineering scheme has been developed in which the entire vaccinia genome is contained in a bacterial artificial chromosome, where it can be engineered and subsequently reactivated by infection of cells infected with a nonreplicating helper fowlpox virus (Domi and Moss 2002).

In the sections that follow, we consider briefly the principles and practice of each of the specific areas of poxvirus genetics described above.

Construction of virus mutants for use in determining the function of individual poxvirus genes

Several laboratories have used classical forward genetic methods to assemble collections of conditional lethal mutants to be used for the study of the function of individual poxvirus genes (reviewed by Condit and Niles 1990). Recently, a complete complementation analysis combining two independent mutant collections has been conducted, resulting in a combined collection of 138 temperature-sensitive mutants comprising 53 complementation groups (Lackner et al. 2003). These temperature-sensitive mutants, along with numerous drug-resistant, drug-dependent, and host-range mutants, have been and will continue to be a powerful resource for determining poxvirus gene function. However, given that the poxvirus genome contains approximately 200 genes, and assuming that approximately 150 of these genes are essential for virus growth in culture, even this combined collection provides only about one-third coverage of the genome. With this in mind, two alternative methods for reverse genetic engineering of mutants in specific poxviral genes have been developed.

One reverse genetic method for creating conditional lethal poxvirus mutants involves regulating transcription of the poxvirus gene of interest using elements from a bacterial operon (Fuerst et al. 1989; Rodriguez and Smith 1990; Traktman et al. 2000). In its simplest form this involves construction of a recombinant poxvirus which constitutively expresses a bacterial repressor protein, for example the *lac* repressor, and which also contains a cognate operator (that is a repressor-binding site) between the transcriptional promoter and the coding sequence of the target gene to be regulated. In such a recombinant the expression of the gene can be controlled by use of an inducer molecule during virus infection, for example IPTG in the case of *lac* repressor control. Appropriate regulation of the target gene sometimes requires more baroque constructions. For example, recombinants can be constructed which contain bacteriophage T7 RNA polymerase under *lac* repressor control, and in which the target gene is regulated by both a T7 RNA polymerase promoter and a *lac* operator (Ward et al. 1995). Numerous inducible recombinant poxviruses have been constructed which have proven invaluable for the study of individual poxvirus genes. One drawback of this approach is that some poxviral genes, most notably early genes, cannot be cleanly regulated.

An alternative approach to creating conditional lethal poxvirus mutants is the construction of temperature-sensitive mutants using clustered charge to alanine scanning mutagenesis (Hassett and Condit 1994). Clusters of charged residues are identified within the linear amino acid sequence of a given target gene, and all of the charged residues in a given cluster are changed to alanine in a cloned copy of the gene. Individual clustered charge to alanine mutants are then recombined into the viral genome and recombinant viruses are tested for temperature sensitivity. Empirically, approximately 30 percent of clustered charge to alanine mutants prove to be temperature-sensitive, theoretically because the charge clusters normally reside on the surface of a protein, and the genetic neutralization of the charge weakens protein–protein interactions. Useful clustered charge to alanine temperature-sensitive mutants have been created in several vaccinia genes which were inaccessible via bacterial operon regulation (Hassett et al. 1997; Demasi and Traktman 2000; Ishii and Moss 2001b; Punjabi et al. 2001).

Use of recombinant poxviruses for protein overexpression

The technical foundation for use of poxviruses to overexpress proteins is a recombinant poxvirus which constitutively expresses the bacteriophage T7 RNA polymerase (called here vvT7) and a target gene which is expressed from a bacteriophage T7 transcriptional

promoter (Fuerst et al. 1986). Depending on the goal of the expression, the target gene may be presented in one of three different forms. The target gene may be contained on a plasmid, in which case expression is achieved by infection with the vvT7 and transfection with the target plasmid. The target gene may be recombined into another poxvirus, in which case expression is achieved by coinfection with vvT7 and the target gene-containing virus. Lastly, the target gene may be recombined into vvT7 itself as described above, providing that the system is under inducible control of a bacterial operon system.

Overexpression of proteins from poxvirus vectors has three principal uses (Moss 1996). First, the system can provide for eukaryotic expression of large quantities of protein for purification and use in biochemical studies (Bayliss and Condit 1995). Second, the system can be used for transient expression of proteins in eukaryotic cells in order to study protein function, for example function of paramyxovirus replication proteins (Smallwood et al. 2002). Third, the system has been used to launch synthesis of viral genomes and viral gene products for construction of recombinant viruses, for example rhabdoviruses (Roberts and Rose 1998).

Use of recombinant poxviruses as vaccine vectors

Infection of animals or humans with recombinant poxviruses which express foreign antigens under the control of poxvirus transcriptional promoters can result in a robust humoral and cellular immune response to the foreign antigen (Paoletti 1996). This strategy has potential for providing immunization against organisms for which conventional vaccines are lacking. Recombinant poxvirus vaccines have been used with clinical success in animals; for example, a vaccinia recombinant that expresses the rabies glycoprotein has been used in the wild to control the spread of rabies virus (Pastoret and Brochier 1996). While recombinant poxvirus vaccines would undoubtedly be effective in humans, none is currently licensed for human use, primarily because of safety concerns associated with the poxvirus vector. Vaccinia vectors with increased safety features have been created by deleting numerous genes nonessential for growth in culture, and alternative poxvirus vectors have been developed, most notably attenuated vaccinia virus strains (Modified Vaccinia Ankara) and avipoxvirus vectors such as canarypox (Paoletti et al. 1995).

POXVIRUS GENES RESPONSIBLE FOR IMMUNE EVASION, HOST RANGE, AND CONTROL OF APOPTOSIS

Poxviruses adopt a wide variety of strategies to ensure survival. These strategies include the shutoff of host transcription, synthesis of different forms of infectious virus particles with differing surface components that facilitate cell spread and viremia, and assembly of virus particles into environmentally resistant inclusion bodies. In addition, as the virus family evolved and became established in different vertebrate hosts or sites within a host, poxviruses developed the means to capture essential host genes which then evolved to target critical aspects of host defenses such as host range, inflammation, and other immunomodulatory mechanisms which serve to enhance virus survival. As described previously, many of these modulatory genes are located within the variable or noncore region of the poxvirus genome and are non-essential for virus growth in cell culture. There has been much speculation as to how poxviruses which develop in the cytoplasm might capture cellular genes. One clue is suggested by the finding that strains of fowlpox virus have incorporated a reticuloendotheliosis virus (a retrovirus) within the fowlpox virus genome (Hertig et al. 1997). It is possible that the reverse transcriptase encoded by a retrovirus might reverse transcribe cellular transcripts which might subsequently be incorporated into the poxvirus genome.

Many of the poxvirus-encoded immune modulatory genes are shared by a number of poxviruses, particularly those that cause similar diseases even though the viruses belong to different genera. However, these genes can also be quite different in the case where two viruses cause very dissimilar disease, as is the case if one compares one of the orthopoxviruses such as vaccinia virus or variola virus to MCV. Both these viruses employ the same basic molecular strategies of replication, transcription, contain the same central core of conserved genes and have a similar genome size. However, variola virus is associated with a severe, generalized disseminated infection with high morbidity and mortality whereas the disease caused by MCV in normal individuals is typically rather benign, albeit persistent, and consists of single or multiple 2–5 mm non-inflammatory, painless, papular, dermal lesions, which can arise on various parts of the body. These lesions may persist for months or longer and frequently resolve without treatment. In immunocompromised individuals, the disease is frequently more severe and causes severe discomfort and disfiguration (Esposito and Fenner 2001) (see Virus infections in immunocompromised patients).

It is likely that the genes contained within the variable regions of these two viruses play a major role in the disease process. In the case of MCV, these genes would be consistent with virus growth restricted to the dermis and be particularly effective against the host immune defenses operative at that site. On the other hand, vaccinia virus or variola virus might be expected to encode an entirely different coterie of genes best suited to overcome immune and host responses directed against an overt generalized infection. While

cautioning against oversimplification, this is a useful model to consider. These genes are summarized in Table 5.

In the discussion that follows, we focus our attention on vaccinia virus, much of which extrapolates to variola virus and to a lesser extent MCV because these are the most significant from the point of view of human disease. Much of what we know about virus-encoded immune modulatory genes encoded by poxviruses causing general, disseminated infections is derived from studies on the prototype orthopoxvirus vaccinia virus and from other poxviruses, most notably leporipoxvirus myxoma virus, and thus must be extrapolated to variola virus. We take note of the fact that there is some data to suggest that variola orthologs of vaccinia virus genes may be particularly attuned to human hosts (Rosengard et al. 2002) in much the same way as myxoma virus immunomodulatory genes tend to be particularly effective within rabbits. In the case of MCV, the virus can not be grown in cell culture so that study of MCV genes must be done either on the expressed and purified protein or following cloning of the MCV gene into a surrogate virus, typically vaccinia virus. There are at least five excellent, comprehensive reviews of poxvirus immunomodulatory proteins (Moss et al. 2000; Moss and Shisler 2001; Shisler and Moss 2001a; Alcami 2003; Seet et al. 2003). The following discussion draws from all these reviews.

General considerations of poxvirus-mediated control of the host response to infection

Generally, the initial exposure of a given host to viruses, including poxviruses, involves macrophage and lymphocytes and leads to inflammation in response to tissue damage and to the production of interferon. Interferon in turn stimulates natural killer (NK) cells which can kill virus-infected cells as a first line of defense in a non-specific fashion independent of the more sophisticated, adaptive immune response. Similarly, the activation of the complement cascade also functions as a first line of defense. Synthesis of antigenic virus proteins are then processed by antigen-producing cells such as dendritic cells and macrophages. This processing generates peptides which then complex with the major histocompatibility complex (MHC) and are presented by these antigen-presenting cells to lymphocytes. There are

Table 5 *Poxvirus immunomodulatory, anti-apoptotic and host range genes*

Virus	Gene		Protein	Description
Molluscum contagiosum virus	**MCV ORF**		**Size (aa)**	**Cellular homolog**
	080R		395	MHC class I α-chain homolog
	033L		579	Thymocyte antigen? CDIc T-cell surface antigen?
	066L		220	Glutathione peroxidase
	159R		241	Caspase-8 and FADD apoptosis-like inhibitor
	148R		104	Chemokine homolog
	054		235	IL-18 binding protein
Vaccinia virus	**VVCOP ORF**	**VACWR ORF**	**Size (aa)**	**Description**
	C3L	*025*	263	Complement control protein
	K3L	*034*	88	eIf2-α homolog
	E3L	*059*	190	dsRNA binding protein
	B8R	*190*	272	IFN-α receptor decoy
	B19R	*200*	353	IFN-α/β binding protein
	Absent	*013*	126	IL-18 binding protein
	B13/14R	*195*	345	Serpin (SPI-/crmA)
	A46R	*172*	240	TIR-like
	A52R	*178*	190	TIR-like
	A53R	*179*	103	TNF-like receptor*
	C22L/B28R	*004, 215*	122	Soluble TNFR
	A41L	*166*	219	Chemokine-binding protein, unknown ligand, anti-inflammatory
	A38L	*162*	277	CD47-like protein
	K2L	*033*	369	Serpin (SPI-3)
	A39R	*163*	295	Semaphorin
	A44L	*170*	346	Hydroxysteroid dehydrogenase
	C23L (*B29R*)	*218*	244	Type II chemokine-binding protein
	B16R	*197*	326	IL-1β binding protein
	C12L/B22R	*205*	353	Serpin (SPI-1)
	K1L	*032*	284	Host range, ankyrin repeat protein
	C7L	*021*	150	Host range, ankyrin repeat protein

a number of lymphocytes including $CD8^+$ T lymphocytes (CTL) that expand to clear infected cells and that comprises the basis of cell-mediated immunity (CMI). There are two types of T-helper cells that contribute to CTL activity. Type I $CD4^+$ helper T lymphocytes are involved in inducing longlasting CTL activity and the type 2 $CD4^+$ helper T lymphocytes interact with B cells to produce neutralizing antibodies, which prevent newly released virus from initiating subsequent infection (humoral immunity). CTLs recognize antigen in conjunction with class I MHC, whereas $CD4^+$ helper cells recognize antigen presented in conjunction with MHC class II (Esposito and Fenner 2001).

Orthopoxviruses have genes designed to neutralize both the interferon and complement responses. There is no evidence to suggest that MCV controls the complement response nor is involved in the control of interferons to anywhere the same degree as the orthopoxviruses. Following the innate response, in a naive host, the CTL response occurs and is primarily responsible for clearing an infection (Buller and Palumbo 1991; Palumbo et al. 1994; Ada and Blanden 1994; Barry and Bleackley 2002). However, antibodies formed soon thereafter may be instrumental in preventing newly synthesized particles from accessing sites not readily accessible to adaptive CTLs such as the skin. Therefore, it is reasonable to assume that virus-coded genes that deflect host responses would be designed not only to interfere with antigen presentation in the context of class I and II MHC but also to interfere with the consequences of that antigen presentation, namely virus clearance and ultimately immunological memory. There is some evidence to suggest that MCV controls the MHC but little evidence to suggest that orthopoxviruses do so directly.

However, a significant and general effort is mounted by all poxviruses against cytokines and chemokines, which are involved in both innate and adaptive immunity. The virus-mediated deflection of these responses serves to mask the infection by various means and 'buy time' during which the infection becomes established. orthopoxvirus-encoded proteins include those that interfere with complement, various cytokines (tumor necrosis factor (TNF), interferons (IFN)-α, β, and γ, interleukins (IL)-1β and IL-18), and Toll-like receptors (TLR) (Table 5). There are also poxvirus proteins designed to bind to and interfere with cellular chemokines as well as poxvirus-encoded chemokine-like molecules. Some of these and additional proteins interfere with aspects of inflammation, apoptosis, and host range. The repertoire of MCV appears to be more limited. As mentioned, it is likely that MCV controls the MHC system. MCV proteins that inhibit apoptosis, an IL-18 binding protein and a chemokine homologue have been identified. Each of these activities is described in more detail below. The orthopoxvirus ORF designation uses the dual nomenclature of vaccinia virus Copenhagen for convenience but cross-referencing to the ortholog in vaccinia WR is shown in Table 5.

Control of the MHC by MCV (MC080 and MC033)

A striking feature of MCV infections is the absence of inflammation at the sites of replication even in immunocompetent individuals (Heng et al. 1989). Also, lesion areas are devoid of NK, Langerhans, and T cells and no longer display β_2-macrogobulin reactivity (Viac and Chardonnet 1990). There are two MCV proteins which could potentially interact with or replace components of the MHC class I system. The *MC080R* gene of MCV encodes an MHC class I (α-) heavy chain homologue, which theoretically could compromise normal MHC class I function. However, the function of the MC080R protein is unclear because complexes of MC080R and β_2-macroglobulin form only at high concentrations of MC080R and are not detected on the surface of cells (Senkevich and Moss 1998). It is also noteworthy that even when complexes were detected under conditions when MC080R was overexpressed, HLA-A2 appears to successfully compete with the MC080R protein for binding to β_2-microglobulin (Senkevich and Moss 1998). Hence the mechanism by which MC080R acts is unclear. The *MC033L* ORF has some homology to thymocyte antigen and to the CD1c T-cell surface glycoprotein but the mechanism of action is unknown.

Myxoma virus, like vaccinia virus, causes a generalized disseminated infection and down-regulates class I MHC epitopes (Boshkov et al. 1992) through the M153R protein. The M153R protein contains a leukemia-associated protein (LAP) domain and localizes to the endoplasmic reticulum and is believed to target β_2-macroglobulin-associated MHC I molecules both at the cell surface and in the post-Golgi compartment for retention and subsequent lysosomal degradation (Guerin et al. 2002). There is little evidence to suggest direct control of the MHC by vaccinia virus. In fact, were MHC presentation significantly affected by vaccinia virus, vaccinia would not be nearly as effective as a vaccine vector as it appears to be (Nash et al. 1999; Moss 2001).

Complement (ORF C3L)

The complement control protein (VCP) was one of the first poxvirus anti-host defense genes discovered (Kotwal and Moss 1988; Kotwal et al. 1990). The protein is characterized by short consensus repeat sequences (SCR) characteristic of complement regulatory proteins (Kotwal and Moss 1988). VCP inhibits both the classical and alternative activation of complement by inhibiting C3b and C4b proteins, which are key in the formation of active complement (Kotwal et al. 1990). VCP also

inhibits the antibody-dependent, complement-mediated neutralization of IMV. Deletion of the *VCP* gene from vaccinia virus leads to production of smaller lesions in infected animals (Isaacs et al. 1992). It is interesting to note that the corresponding variola virus gene is much more efficient than the vaccinia VCP in inhibiting human complement (Rosengard et al. 2002). Another orthopoxvirus protein that contains SCRs, is the *B5R/VACV-WR_187* gene product (Takahashi-Nishimaki et al. 1991; Engelstad et al. 1992). B5R is a component of EEV membranes but is not found in IMV (Herrera et al. 1998). Despite the presence of SCRs, B5R does not appear to exert any effects on complement.

Interferons (IFN) (ORFs B8R, E3L, and K3L)

IFN-γ

The role of IFNs in controlling virus infections is well known. IFNs regulate a number of intracellular signaling pathways through kinase activation and these pathways are targeted in some fashion by both the orthopoxviruses and MCV, albeit differently. IFN-γ acts to up-regulate the double-stranded RNA-dependent protein kinase, phosphokinase R (PKR), a key component in cellular signaling pathways. In the case of orthopoxviruses, IFN-γ action is regulated both intracellularly by the *K3L* and *E3L* genes and extracellularly by a soluble, secreted type II IFN receptor (B8R).

The orthopoxvirus-secreted IFN-γ receptor (B8R) serves as an IFN-γ decoy binding protein, which acts to sequester IFN-γ and to prevent productive binding of the cytokine to cellular receptors. This decoy protein, typical of many 'viroceptors,' contains sequences similar to the cytokine-binding domain but lacks the transmembrane and cytoplasmic signaling sequences. While the vaccinia IFN-γ receptor decoy binds IFN-γ from many species, a similar protein isolated from myxoma virus binds only rabbit IFN-γ, indicative of adaptation to the rabbit host (Mossman et al. 1995) and the comparable gene of ectromelia virus is specific for mouse IFN-γ (Smith and Alcami 2002). Deletion of the IFN-γ receptor from vaccinia virus leads to attenuation of the virus in mouse models (Verardi et al. 2001).

The proteins E3L and K3L are involved in anti-host defense strategies that regulate the IFN responses through accessory cellular proteins including PKR, a protein induced by IFN, and the enzyme 2′,5′-oligoadenylate synthetase (OAS) (Sen 2001). Both E3L and K3L can effectively prevent PKR-mediated inhibition of protein synthesis at the level of RNA or translation, respectively. The intracellular *K3L* gene, which resembles the protein translation factor eIF2α, acts as a nonfunctional substate for PKR, which is induced by IFN-γ (Davies et al. 1993). The *E3L* gene encodes a double-stranded RNA-binding protein of either 20 or 25 kDa. Hence, by binding double-stranded RNA, the E3L protein prevents double-stranded RNA activation of PRK (Chang and Jacobs 1993; Yuwen et al. 1993). There is also some evidence to suggest that E3L can interact directly with PKR to form an inactive heterodimer (Romano et al. 1998). The binding of E3L to dsRNA also serves to abrogate activation of OAS. Initially synthesized as an inactive enzyme, OAS requires dsRNA for activation, a step also prevented by the binding of E3L to dsRNA. Once activated, OAS synthesizes 2′–5′-linked oligoadenylate which serves as a cofactor for ribonuclease L. Ribonuclease L cleaves both ribosomal and mRNA, leading to inhibition of protein synthesis at the RNA level. Deletion of the *E3L* gene has a major effect on virulence and deletion of either gene leads to a reduced host range of the virus which is discussed further under poxvirus genes that affect host range.

As is discussed below, like IFN-γ, IL-β is also controlled in an intra- and extracellular fashion. The dual means by which the virus acts to prevent the action of these cytokines suggests that the pathways controlled by these cytokines are very important in counteracting the virus infection.

IFN-α/β

Orthopoxviruses, including variola virus, encode a type I interferon binding protein (ORF B19R) which binds both IFN-α and β (Symons et al. 1995). Unlike the IFN-γ soluble receptor just described, this protein has little or no similarity to the cellular counterpart. A folding of the immunoglobulin domains contained in the viral IFN-α/β binding protein and the fibronectin type III domains of the cellular receptor have been proposed to account for their interaction with the same ligands (Alcami 2003). The protein binds to and inhibits the type I interferons IFN-α,β as well as IFN-δ and ω (Symons et al. 1995; Liptakova et al. 1997; Vancova et al. 1998; Smith and Alcami 2002). Deletion of the gene leads to attenuation of the virus (Verardi et al. 2001).

Interleukin (IL)-18-binding proteins (VACV-WR_013, MC054)

The IFN pathway is targeted indirectly by proteins which bind to and functionally eliminate IL-18, a potent inducer of IFN-γ. An IL-18-binding protein is encoded by some but not all strains of vaccinia virus and is absent in strain Copenhagen (Symons et al. 2002). This protein also has little or no sequence similarity to the cellular IL-18-binding protein. An equivalent protein is encoded by MCV. Originally, IL-18 was identified as a powerful inducer of IFN-γ, but also induces the synthesis of a number of the cytokines and chemokines, which in turn can influence the Th1 or Th2 cellular response and influence activation of NK and cytotoxic T cells

(Nakanishi et al. 2001). Deletion of the IL-18-binding protein encoded by vaccinia virus WR results in attenuated infections (Symons et al. 2002). Deletion of the IL-18-binding protein gene encoded by ectromelia virus, a pathogen of mice, also resulted in virus attenuation (Born et al. 2000).

The MCV genomic sequence indicates that none of the plethora of soluble cytokine-receptor or cytokine-binding proteins or decoy receptors found in the orthopoxviruses are encoded by MCV. However, as stated above, the virus does encode an IL-18-binding protein (MC054) (Xiang and Moss 1999). Strong binding of IL-18 has been observed with MC054 (Xiang and Moss 1999). Two additional MCV proteins encoded by ORFs, MC051 and MC053, are related to MC054, but these two proteins lack conserved residues associated with high-affinity binding to IL-18. Therefore, it is likely these two proteins bind other ligands (Xiang and Moss 2001). Unlike the orthopoxvirus IL-18-binding proteins, the MC054 protein contains a long C-terminal extension. The C-terminal tail binds with high-affinity to glycosaminoglycans and hence to cell surfaces (Xiang and Moss 2003). MC054 contains a furin cleavage site which separates the glycosaminoglycan-binding C-terminal tail of the molecule from the IL-18-binding portion of the protein (Xiang and Moss 2003). This allows for a secreted as well as cell-bound form of the IL-18-binding protein. It has been proposed that the C-terminal tail may function to alter the half-life of the IL-18-binding protein and serve to concentrate the protein in the vicinity of MCV-infected cells where it is most needed. The cleaved form may allow IL-18 binding and sequestration activity to leave the site of infection for activity at distal sites.

Interleukin (IL)-1β (ORFs B16R, B13R/B14R, A46R, and A52R)

Vaccinia virus encodes a secreted IL-1β-decoy receptor (ORF B16R), (Alcami and Smith 1992; Spriggs et al. 1992) but interestingly, the gene is present but inactive in all variola virus strains examined to date. This decoy receptor binds IL-1β but not IL-1α or the host IL-1 receptor antagonist (Alcami and Smith 1992; Spriggs et al. 1992; Smith and Alcami 2000). Deletion of this gene from vaccinia virus suggested that IL-1β serves to control fever during poxvirus infections (Alcami and Smith 1996). Virus lacking a functional B16R is attenuated when animals are infected via the intracranial route (Spriggs et al. 1992) but exhibits enhanced virulence during intranasal infections (Alcami and Smith 1992).

IL-1β, like IFN-γ, is also regulated both intracellularly as well as extracellularly. In the case of IL-β, intracellular regulation is mediated by one of the three virus-encoded serpins, crmA/SPI-2 (ORF B13R/B14R). The protein encoded by crmA/SPI-2 is a potent inhibitor of caspases-1 and 8 and perhaps 10 as well as granzyme B. Hence this protein has the unusual property of inhibiting both serine (granzyme B) and thiol proteases (caspases). Caspase-1 is responsible for synthesis of active, proinflammatory IL-1β from the inactive precursor proIL-1β (Ray et al. 1992) as well as activating IL-18 from proIL-18 (Gu et al. 1997). Therefore, crmA/SPI-2 can influence the levels of both IL-β and IL-18. The ability to inhibit caspase-8 can serve to block apoptosis via several pathways including not only extrinsically induced apoptosis induced by Fas/Fas ligand and granzyme B, but also apoptosis intrinsically mediated by caspase-8. However, deletion of this gene from vaccinia virus or cowpox virus leads to only modest attenuation (Tscharke et al. 2002).

Finally, IL-β can potentially be regulated intracellularly in one additional way. After ligand engagement, IL-1β receptor-mediated signaling can be disrupted by poxvirus proteins that contain signaling components of Toll-like receptors (TLR). TLRs are important in innate immunity and serve as pattern recognition receptors on cells of the innate immune system (O'Neill 2000). Variola virus encodes one such gene, vaccinia virus two (*A46R* and *A52R*). Each of these proteins contains a Toll/IL-1 receptor (TIR) domain motif within the cytoplasmic portion of the molecule which allows for interaction with adaptor molecules to prevent intracellular signaling downstream of the IL-1 receptor (Bowie et al. 2000). Of the two vaccinia proteins, A52R appears the more effective in inhibiting activation of NF-κB, a transcription factor involved in cytokine expression (Bowie et al. 2000). As might be anticipated, proteins such as A52R appear to endow the virus with the ability to inhibit a number of signaling pathways which are initiated from TIR domain-containing cell surface receptors such as TLRs and IL-1R (Harte et al. 2003). Deletion of A52R from vaccinia virus has no effect on growth or plaque size but the virus is attenuated in intranasally infected mice as evidenced by milder signs of illness and less weight loss (Harte et al. 2003).

Tumor necrosis factor (TNF) (ORFs C22L, B28R)

TNFs are potent proinflammatory cytokines secreted by macrophages and activated T cells comprise a family of powerful proinflammatory cytokines (Smith et al. 1994). There are at least three classes of TNFs: TNF, lymphotoxin (LT)-α and LT-β. All are active as trimers that recognize two members of the superfamily of TNF receptors (TNFR), TNFRI (p55) and TNFRII (p75). The main effect of host-encoded TNF is to induce an antiviral state that controls lysis of infected cells (Locksley et al. 2001). Poxviruses encode a number of homologues of the TNFR

and some viruses, for example cowpox virus, encode four (Hu et al. 1994; Smith et al. 1996; Loparev et al. 1998; Saraiva and Alcami 2001) designated as CrmB, CrmC, CrmD and CrmE (Cunnion 1999; Saraiva and Alcami 2001). Variola virus also encodes a TNFR homologue as does vaccinia virus strain Lister; however, many vaccinia strains lack any TNF receptor homologue (Alcami et al. 1999). Vaccinia virus strain Copenhagen encodes an inactive gene, which, because it is located in the TIR of the genome, is present in two copies (*C22L*, *B28R*). These virus-coded TNFRs have sequence similarity to extracellular domains of both p55 and p75 of the host cell but lack the anchoring C-terminal transmembrane domain that anchors the cellular protein on the cell surface (Smith et al. 1991; Upton et al. 1991; Schreiber et al. 1996; Loparev et al. 1998). These molecules function as decoy TNF-binding proteins, binding TNF to prevent TNF from interacting with the appropriate cellular receptor (Cunnion 1999; Xu et al. 2000). Another member of this family of proteins, found in cowpox virus, is a protein called VD30, which resembles cellular CD30 and binds to the cognate cellular target CD153 (Panus et al. 2002). In the case of myxoma virus, deletion of the viral TNFR homologue gene leads to a strong attenuation of the virus (Upton et al. 1991).

Regulation of chemokines (ORFs C23R, B29R, and MC148R)

Chemokines are small molecules generally involved in attracting leukocytes to the site of damage produced in response to various cellular insults including infection. However, within the context of virus infection, there are numerous possibilities for the possible function of virus-encoded chemokines and chemokine receptors (Alcami 2003). Chemokine agonists might attract leukocytes capable of supporting virus infection or induce migration of Th2 cells and thereby alter the immune response to infection. Chemokine agonists might also induce angiogenesis and/or contribute to infection pathology. Virus-encoded antagonists might prevent migration of immune cells (Th1 cells) that lead to an antiviral response. The regulation of chemokines may also alter critical signaling pathways in such a way as to promote virus infection. Viral-encoded chemokine receptors could lower the concentration of critical cytokines at localized sites of infection and could down-regulate the production of the chemokine itself, which would allow for immune evasion. Cellular-bound chemokine receptors could, in response to the appropriate chemokine, lead to migration of the particular cell leading to spread of the viral infection. Finally, the receptors could induce expression of chemokines and thereby modulate the immune response or contribute to immunopathology. The poxviruses have the potential to regulate these responses by encoding chemokine-binding proteins, chemokine receptors, or chemokine ligand mimics (Kotwal 2000; Lalani et al. 2000; Mahalingam and Karupiah 2000; Mahalingam et al. 2000; Murphy 2001). Binding proteins have been grouped into low-affinity (type I) and high-affinity chemokine-binding proteins (type II). Orthopoxviruses encode a high-affinity (type II) binding protein found in two copies within the ITRs in vaccinia virus (C23R, B29R) but only one copy in variola virus, which has far smaller ITRs. This protein, also called vCCI or CBR II, binds CC chemokines but not CXC or C chemokines. The binding to CC chemokines serves to prevent binding of the CC chemokines to the appropriate G-protein-coupled receptor (Graham et al. 1997; Smith et al. 1997; Alcami et al. 1998; Smith and Alcami 2000). The orthopoxvirus protein binds to a large variety but not all CC chemokines (Burns et al. 2002). Despite the ability to bind to a wide spectrum of CC chemokines, disruption of the gene in vaccinia virus leads to only modest attenuation but an increased leukocyte infiltration (Martinez-Pomares et al. 1995; Graham et al. 1997; Lalani et al. 1999).

Rather than encode chemokine-soluble receptors or binding proteins, MCV encodes a chemokine homologue (MC148R) (Senkevich et al. 1996). The protein is a secreted 104 amino acid protein related to the CC-chemokine family (Bugert et al. 1998) but contains an N-terminal deletion which precedes a dicysteine motif that is critical for activation of receptors. Therefore, the protein can engage or titrate receptors in a nonproductive fashion and function as an antagonist. Indeed, the protein inhibits binding, signaling, and chemotaxis of leukocytes to various CC and CXC chemokines (Krathwohl et al. 1997; Damon et al. 1998). While the protein has only been studied in the context of vaccinia virus recombinants, or as a purified protein, it can be argued that MC148R exhibits anti-inflammatory effects because it can inhibit allograft rejection in transgenic mice (DeBruyne et al. 2000).

3β-Hydroxysteroid dehydrogenase (ORF A44L)

The A44L protein catalyzes the synthesis of immunosuppressive steroids and is capable of converting pregnenolone to the steroid hormone progesterone (Moore and Smith 1992). Deletion of this gene from vaccinia virus leads to somewhat smaller dermal lesions and attenuation (Moore and Smith 1992; Sroller et al. 1998; Tscharke et al. 2002).

Semaphorin (A39R)

Semaphorins are a highly conserved family of regulatory proteins defined by the presence of a SEMA domain and an extracellular component that determines receptor-binding specificity. Semaphorins can be anchored to membranes, occur as transmembrane

components, or be secreted (Spriggs and Sher 1999; Tamagnone and Comoglio 2000). Semaphorins originally were not associated with the immune system; they serve as axonal guidance clues in the developing nervous sytem. However, they also serve as chemoattractants or chemorepellants in the immune system. Recent evidence suggests additional roles for semaphorins in regulating the immune response. The semaphorin SEMA4D (CD100) SEMA4D (CD100), expressed constitutively by T cells, enhances the activation of B cells and dendritic cells (DC) through its cell-surface receptor, CD72. SEMA4A, when expressed by DCs, is involved in the activation of T cells through interactions with TIM2. Emerging evidence indicates that additional semaphorins and related molecules are involved in T-cell antigen-presenting cell (APC) interactions (Kikutani and Kumanogoh 2003). The vaccinia virus protein (A39R) encodes a 55 kDa protein with 25 percent homology to cellular semaphorins (Kolodkin et al. 1993; Comeau et al. 1998). It is believed that the A39R protein interacts with an appropriate semaphorin protein receptor, VESPR (also referred to as CD232 or plexin C1) to induce production of the cytokines IL-6 and IL-8 to control inflammation (Comeau et al. 1998). Deletion of the gene from vaccinia virus led to increased size and prolonged persistence of skin lesions but in a virus-strain-dependent manner (Gardner et al. 2001). It has been suggested that the protein has direct or indirect proinflammatory effects (Gardner et al. 2001).

Serpins

Orthopoxviruses encode three serpins (serine proteinase inhibitors) designated as SPI-1 (C12L), SPI-2/crmA (B13R/B14R), and SPI-3 (K2L). The leporipoxviruses also encode three serpins, designated SERP1, SERP2, and SERP3. The number of serpins encoded by an individual virus can vary. The avipoxviruses can encode five or more. The serpin most universally distributed appears by sequence to be an ortholog of SPI-2/crmA. SPI-2/crmA is functionally very similar to SERP2 and SPI-3 is very similar to SERP1. MCV encodes no serpins.

SPI-3

SPI-3 (K2L, VACWR033) and SERP1 of myxoma virus are biochemically very similar. The proteinases inhibited by SERP1 include plasmin, tissue plasminogen activator, urokinase, and thrombin (Lomas et al. 1993; Nash et al. 1998). These proteases are the same as those inhibited by the SPI-3 protein even though the two proteins are only 29 percent identical (Turner et al. 2000). Nevertheless, SPI-3 can not replace SERP1 to maintain virulence in myxoma virus (Wang et al. 2000) and deletion of SPI-3 from vaccinia virus or cowpox virus leads to little if any attenuation of the virus in animals. SPI-3 inhibits orthopoxvirus-infected cell fusion, a property absent in SERP1 (Wang et al. 2000). The myxoma virus SERP1 is an extremely powerful anti-inflammatory protein (Upton et al. 1990; Macen et al. 1993) which when deleted leads to increased inflammation and a marked attenuation and more rapid clearance of myxoma virus in rabbits (Upton et al. 1990; Macen et al. 1993). Purified SERP1 has been shown to prevent inflammation following balloon angioplasty (Lucas et al. 1996; Liu et al. 2000) and allograft and xenograft transplant rejection in animal models (Miller et al. 2000).

SPI-2/CRMA

The *SPI-2* gene (*B13R/B14R* in vaccinia virus), was originally discovered in cowpox virus where the gene was designated as *crmA*. The role of this protein in regulating IL-1β and IL-18 has been discussed earlier in this chapter. In addition to being an effective inhibitor of caspase-1, it is also an effective inhibitor of caspase-8 and perhaps caspase-10. Inhibition of caspases-8 and/or 10 targets key apical caspases in the pathways of apoptosis, initiated by caspase-8, TNF- or Fas-ligands (Enari et al. 1995; Tewari and Dixit 1995; Dobbelstein and Shenk 1996; Kettle et al. 1997). This serpin can also inhibit the serine protease granzyme B, a product of NK and cytotoxic T cells, delivered to target cells to initiate perforin-dependent apoptotic killing (Quan et al. 1995; Tewari et al. 1995). Therefore SPI-2/crmA is referred to as a cross-class inhibitor because of activity against both thiol and serine proteases. This cross-class specificity is shared by the myxoma virus SERP2 protein (Turner et al. 1999). Deletion of SERP2 from myxoma virus leads to attenuation, increased inflammation, and apoptosis of lymphoid cells (Petit et al. 1996; Messud-Petit et al. 1998). Despite the overt functional similarities between SERP2 and the orthopoxvirus SPI-2/crmA, deletion of the gene from vaccinia virus (Kettle et al. 1995) or cowpox virus (Thompson et al. 1993) leads to little if any attenuation of intranasal virus infection of animals. However, when virus is introduced into the ear pinnae of the mouse, deletion of the *SPI-2/crmA* gene leads to enhanced virulence (Tscharke et al. 2002). In addition to serpin-mediated inhibition of apoptosis, a second activity, as yet unidentified, also directly modulates the mitochondrial apoptotic pathway by influencing the permeability transition core (Wasilenko et al. 2001).

SPI-1

Although grouped for simplicity with the other serpins, the *SPI-1* gene is best known as a host-range gene and is discussed below.

Host-range genes

SPI-1 (ORF *C12L/B22R*)

The orthopoxvirus serpin SPI-1 inhibits cathepsin G, a major constituent of neutrophils (Moon et al. 1999) and

deletion of the gene leads to loss of the ability of the virus to grow on human and swine cells (Ali et al. 1994). The phenotype conferred on infected cells appears perhaps to be virus dependent. In the case of RPV, infection of nonpermissive human cells leads to viral DNA replication and full expression of viral proteins and an apoptoticlike phenotype (Brooks et al. 1995) but with vaccinia virus, the nonpermissive infection was characterized by very low levels of intermediate and late viral mRNAs (Shisler et al. 1999). Deletion of the gene from the virus has only modest effects on virulence (Blake et al. 1995).

K3L AND *E3L*

The orthopoxvirus genes *K3L* and *E3L* have been previously discussed in the context of their involvement in controlling the interferon response. They are also required for broad virus host range. The *E3L* gene product, which binds double-stranded RNA, is required for replication in HeLa cells, but not BHK cells. The *K3L* gene functions as a competitive inhibitor for eIF2α phosphorylation. BHK cells are believed to contain relatively low levels of PKR. It is believed that during infection of BHK cells, there are sufficient levels of *K3L*, even in the absence of *E3L*, to prevent activation of PKR, thus offering an explanation for why *K3L* is required for replication in BHK cells. The reverse situation exists for HeLa cells where *E3L* is required. In this situation, the levels of *E3L* are sufficient to sequester all virus-induced dsRNA, alleviating the need for *K3L* (Langland and Jacobs 2002). Infection of nonpermissive cells with virus deleted for *E3L* also leads to apoptosis and the virus is profoundly attenuated when used to infect mice either intracranally or intranasally (Brandt and Jacobs 2001). Infection of nonpermissive cells with virus deleted for *K3L* also leads to apoptosis but the virus has not yet been tested in mice (B. Jacobs, personal communication).

CHOHR (*CP77*), *K1L*, AND *C7L*

Three orthopoxvirus host-range genes have been identified. All three gene products contain ankyrin repeats. The genes are dissimilar in size and sequence but are functionally related. The *CP77* gene of cowpox virus encodes a 77 kDa protein that confers on the virus the ability to grow on Chinese hamster ovary (CHO) cells (Spehner et al. 1988). The corresponding gene is present intact in variola virus (*D6L*, Garcia strain) but is truncated and nonfunctional in vaccinia virus strain WR (*B24L*) and deleted in vaccinia virus Copenhagen. Vaccinia can not grow on CHO cells. The *K1L* and *C7L* genes which encode 30 and 17 kDa proteins, respectively, and the *CP77* gene are under certain conditions functionally interchangeable and somewhat hierarchical in terms of control of host range. Each will allow growth of virus in porcine or human cells. Similarly, the *K1L* and *CP77* genes are interchangeable in that both allow virus growth in RK13 cells. Defects in *K1L* (Ink et al. 1995; Chung et al. 1997) have been linked to induction of apoptosis during infection of the respective nonpermissive cells, but apoptosis is likely not the primary cause of the abortive infection. When virus defective in *K1L* is used to infect nonpermissive RK13 cells, early transcripts are synthesized but early protein synthesis is arrested (Ramsey-Ewing and Moss 1996; Chung et al. 1997). Vaccinia virus infection of CHO cells is characterized by a block in the translation of intermediate mRNAs which prevents synthesis of late mRNAs (Ramsey-Ewing and Moss 1995). There appears to be no effect of either the the *K1L* or *CP77* gene in animal models (Chen et al. 1992, 1993). Less is known about the function of the *C7L* gene (Oguiura et al. 1993).

Inhibition of apoptosis

A number of the genes previously discussed control apoptosis. These include the orthopoxvirus caspase and granzyme B inhibitor *SPI-2/crmA*. Viral proteins which target the IFN response pathway, such as the decoy receptors and the *E3L* and *K3L* genes, can also be viewed as inhibitors of apoptosis because induction of both PKR and OAS which are intimately controlled by these viral proteins also induce apoptosis by activating caspase-8 (Gil and Esteban 2000). MCV encodes some unique regulators of apoptosis.

MC66

The MC66 ORF encodes an inhibitor of ultraviolet- or peroxide-mediated apoptosis (Shisler et al. 1998). The protein has homology to human glutathione peroxidase and is a member of the class of selenocysteine-containing proteins (Moss et al. 2000) that can be considered to function as an antioxidants. This MCV selenoprotein protects human keratinocytes against the cytotoxic effects of ultraviolet irradiation and hydrogen peroxide, providing a mechanism for a virus to defend itself against environmental stress. Enzymes such as these convert hydrogen peroxide into water and oxygen, which together with catalase and superoxide dismutase reduce levels of oxygen-reactive metabolites, which if left unchecked, would damage the cellular environment or induce apoptosis.

MC159R

Both MC159R and the related protein M160R each contain two death effector domains (DED) (Senkevich et al. 1997), which are critical motifs involved in regulating apoptosis. MC159 binds to Fas-associated death domain (FADD) as well as procaspase-8 and acts to protect transfected cells against death effector filament formation and apoptosis induced by either Fas ligand or TNF-α (Bertin et al. 1997; Hu et al. 1997; Thome

et al. 1997; Tsukumo and Yonehara 1999). Proteins such as this are referred to as viral FLICE inhibitory proteins (vFLIP) because of their ability to complex with procaspase-8 or FADD to prevent activation of procaspase-8 to active caspase-8. The function of MC160R, despite having two DED domains, is less clear. While the MC160R protein does have some anti-apoptotic activity, it is weak (Hu et al. 1997). Furthermore, the protein undergoes degradation by caspases in the absence of MC159R, indicating that one role of MC159R is to stabilize MC160R (Shisler and Moss 2001b).

INTRODUCTION

Influenza viruses are unique in their ability to cause recurrent seasonal epidemics of varying severity, as well as global pandemics during which acute febrile respiratory disease occurs explosively in all age groups. Excess hospitalization and death often accompany less serious but widespread morbidity during both seasonal epidemics and pandemics of influenza.

Two features of influenza virus replication and evolution account for much of the epidemiological success of these viruses. First, there is the ability of novel influenza A viruses that circulate naturally in avian reservoirs to emerge unpredictably, either through genetic reassortment or through direct transmission, and spread in a naïve human population to cause an influenza pandemic. Second, there is the relatively rapid and unpredictable antigenic change that accompanies the evolution of influenza viruses once they have become established in humans. Although influenza viruses have been studied intensively for more than 70 years and have often been used as a research model for other pathogens, much remains to be learned about influenza virus replication, pathogenicity, epidemiology, immunology, and the factors that lead to the development of influenza pandemics.

Historical record

Influenza has probably existed from antiquity, although the lack of specific pathognomonic signs makes this assertion less definite than in the case of smallpox or cholera (Kilbourne 1987). Even so, historical records of rapidly spreading 'catarrhal fevers' in Great Britain (Table 1) suggest that major influenza epidemics affected human populations as early as the sixteenth century. Pandemic outbreaks are probably a more recent development, paralleling the increases in the world population and the growth of mass transportation systems. Animals may have played a leading role in past influenza epidemics. In the eighteenth and nineteenth centuries, for example, outbreaks of respiratory disease among horses were recorded concurrently with outbreaks in humans (Table 1). Although direct evidence for horse-to-human transmission of influenza viruses is lacking, the sizeable concentrations of these animals near previous centers of human population makes them attractive candidates as disease intermediaries (Hirsch 1883). In modern times, pigs have been accorded a prominent role in the generation of major influenza outbreaks (Goldfield et al. 1977; Scholtissek et al. 1985) (see 'Ecology of influenza'). Until recently, direct avian-to-human transmission associated with fatal outcome in infected individuals was believed not to occur. This changed in 1997 when 18 individuals – six of whom died – were infected with H5N1 avian viruses in Hong Kong (Claas et al. 1998a, b; Subbarao et al. 1998). Since then, direct avian-to-human transmission has been reported in several other incidents, such as human infection with H7N7 avian virus in the Netherlands in 2003 (Fouchier et al. 2004; Koopmans et al.

Table 1 *Influenza: a summary of major epidemics affecting Great Britain and other regions of the world, 1510–1890*

Epidemic year(s)	Season	Prevalence[a]	Temporally associated animal disease	Anomalous symptoms
1510	...	Pandemic	Murrain in cattle	'Gastrodynia'
1557	Autumn	Pandemic	...	Double tertian fever
1580	Autumn	European	Murrain in beasts (Kent)	Parotid swelling
1658	Spring	Britain, Europe	...	'Cephalic affection'
1675	Autumn	Britain, Europe	...	...
1688	...	Dublin	'Nasal defluxin' in horses	...
1693	Autumn	Britain, Europe	Antecedent nasal discharge in horses	...
1710	Spring	Britain, Europe	...	'Quick pulse'
1729	Winter	England, Europe	...	...
1732/3	Spring to winter	Pandemic	Cough in horses	Parotid swelling
1737/8	Autumn	England, Europe, North America	'Disease among horses'	...
1743	Spring	Britain, Europe	'Cough among horses'	...
1758	Autumn	North America, Europe, Britain	...	...
1762	Autumn	Britain, Europe	Antecedent 'horse colds' (1760)	Variable mortality
1767	Summer	Britain, Europe, North America	Dogs and horses, horse cold	...
1775	Autumn	Pandemic	Disease in dogs and horses	Prurigo, erysipelas, pustules
1782	Spring	Pandemic	...	...
1802/3	Spring	Britain, Europe	Cattle and domestic animals	'Interchanging with scarlatina'
1833	Spring	Pandemic	Concurrent disease in horses	...
1836/7	Winter	Pandemic	...	...
1847/8	Autumn	Pandemic	...	...
1889/90	Winter	Pandemic	...	Increased mortality age 20–60 (Jan. 1890)

From Kilbourne (1987).
a) Pandemic implies historical evidence of involvement of more than two continents.

2004) or H5N1 avian viruses in Hong Kong in 2003 (Peiris et al. 2004) and in Vietnam and Thailand where 42 cases and 30 deaths were reported through September of 2004 (Tran et al. 2004) (www.who.int/en/). Although only limited human-to-human transmission occurred, these episodes clearly emphasize the crucial role of avian species in influenza virus epidemiology.

Seroarcheology

Testing of sera from older adults for influenza virus antibodies (so-called seroarcheology) had suggested that the influenza in humans between 1889 and 1898 was caused by influenza A(H2N2) viruses (see Classification section), whereas epidemics or pandemics occurring in 1899–1917 and in 1918–1957 were the result of H3N8 and H1N1 viruses, respectively (Masurel and Marine 1973; Masurel and Heijtink 1983; Mulder et al. 1958; Noble 1982; Rekart et al. 1982). A more recent careful analysis of data from these earlier publications, using the clearly documented emergence of H1 viruses in 1918 as a model, indicates that the H3 subtype is linked to the pandemic of 1889–91, not that of 1900 as often quoted, and that the H2 subtype was unlikely to have caused a pandemic in the late 1800s (Dowdle 1999). Recent pandemic strains share the hemagglutinin (HA) and neuraminidase (NA) subtypes of these earlier strains; however, they are probably not direct descendants, as they show a close relationship to avian viruses (Scholtissek et al. 1978c; Webster and Laver 1972). Thus, the similarity of the HAs and NAs of recently circulating human viruses to those of the past may reflect certain properties of the surface molecules that favor viral replication in human hosts. Indeed, of the many HA and NA subtypes maintained in nature, only three had become established in humans: H1N1, H2N2, and H3N2 subtypes. However, a reassortant H1N2 virus emerged in the human population in 2001 (Gregory et al. 2002), and has since become established (Figure 1).

Virus isolation

The historical record of influenza viruses remained sparse until technological advances permitted their isolation. In 1901, a 'filterable agent' was isolated from chickens suffering from fowl plague (it was later classified by

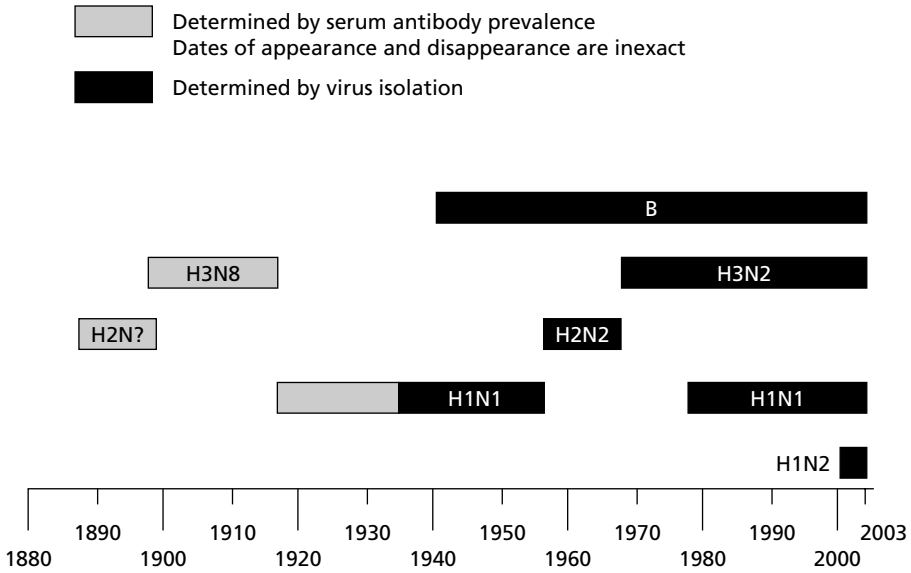

Figure 1 *Eras of prevalence of influenza A and B viruses. The periods designated in black were defined by virus isolation while the periods designated in gray were approximated by determining serum antibody prevalence in retrospective serological studies.*

Schäfer (1955) as an influenza A virus). Smith et al. (1933) inoculated ferrets intranasally with human nasopharyngeal washes, which produced a form of influenza that spread to the animals' cage mates. The human virus [A/Wilson-Smith(WS)/33(H1N1)] was transmitted from an infected ferret to a junior investigator on the project (later Sir Charles Stuart-Harris), from whom it was subsequently re-isolated. An antigenically distinct virus, isolated by Francis (1940), was classified as a type B strain (B/Lee/40) to distinguish it from the 1933 isolate. The third major type of influenza virus, influenza C, was first isolated in 1947 by Taylor (1949).

Major research advances

Influenza research gained enormous momentum when it was shown that the virus could be isolated by inoculating samples into the chorioallantoic membrane of fertilized hens' eggs (Burnet 1940; Francis and Magill 1937). Hirst (1941) and McClelland and Hare (1941) discovered that influenza virus particles agglutinate the erythrocytes of fowl as well as of other animal species. This advance established the concept of hemagglutinin inhibition in the detection of specific serum antibodies, making it possible to distinguish between viruses of the same type. Hirst (1950) further demonstrated the presence of a receptor-destroying enzyme, now known as neuraminidase. Later biochemical work (Gottschalk 1957) revealed that influenza viruses contain the HA and NA as major structural and antigenic components of the virus particle.

Subsequent advances included identification of the segmented nature of the RNA genome and assignment of corresponding protein products (McGeoch et al. 1976; Palese 1977); discovery of the antiviral compound amantadine (Davies et al. 1964); introduction of 'split' and subunit vaccines (Webster and Laver 1966); experimental work on cold-adapted vaccines; and elucidation of influenza gene replication (Inglis et al. 1979; Krug et al. 1979; Lamb and Choppin 1979). More recently, the viral genome has been completely sequenced; the three-dimensional structures of the HA (Wilson et al. 1981) and the NA (Varghese et al. 1983) have been resolved by X-ray crystallography; or the ion channel activity of the M2 protein discovered (Pinto et al. 1992; Sugrue et al. 1990b).

The establishment of reverse genetics techniques that allow the artificial generation of virus from cloned cDNA provided perhaps the most significant stimulus to influenza research in the past two decades. In 1989, a virus was generated that contained a viral RNA segment derived from cloned cDNA (Luytjes et al. 1989), followed by the generation of influenza A virus entirely from plasmids in 1999 (Fodor et al. 1999; Neumann et al. 1999). These techniques facilitated studies of the role of influenza virus proteins in the viral life cycle, identification of the determinants of viral pathogenicity, development of influenza virus vaccines, and exploration of influenza virus as a vaccine vector.

Despite this progress, much remains to be learned about influenza viruses, particularly the molecular mechanism of influenza pathogenesis, interaction between viral and host gene products, and the mechanisms giving rise to new pandemic strains.

CLASSIFICATION

The *Orthomyxoviridae* family consists of five genera: *Influenzavirus A*, *Influenzavirus B*, *Influenzavirus C*,

Thogotovirus, which includes the *Thogoto virus* and *Dhori virus*, and *Isavirus*, which includes infectious salmon anemia virus (ISAV) (Klenk et al. 1995; van Regenmortel 2000). Orthomyxoviruses (Greek: orthos, straight or correct; myxa, mucus) contain segmented, linear, and negative-sense (complementary to mRNA) single-stranded RNA. The number of RNA segments differs among the genera: eight for influenza A, B and ISAV, seven for influenza C, six for *Thogoto virus*, and probably seven for *Dhori virus*. Accordingly, influenza A and B viruses contain HA and NA activities in different glycoproteins, whereas influenza C viruses lack NA, containing instead a hemagglutinin–esterase fusion (HEF) protein. *Thogoto virus* and *Dhori virus* possess a single glycoprotein (GP) that is not related to any known influenza virus protein but is related to the gp64 glycoprotein of baculoviruses (Morse et al. 1992). The virion has a molecular weight of 250 000 kDa and buoyant density in aqueous sucrose of 1.19 g/cm^3. Virions are sensitive to heat, lipid solvents, non-ionic detergents, formaldehyde, irradiation, and oxidizing agents.

Influenza A viruses are further classified into subtypes based on the antigenicity of their HA and NA molecules. Currently, there are 16 recognized HA subtypes (Fouchier et al. 2005) (H1, H2, etc.) and nine NA subtypes (N1, N2, etc.). The full nomenclature (WHO Memorandum 1980) for each new isolate includes the type of virus, the host of origin (except for human), geographical site of isolation, strain number, and year of isolation. The antigenic description of the HA and NA is given in parentheses. For example, a type A virus isolated in Memphis, Tennessee, from a mallard duck in 1995 with a strain number of 123 and an H3N8 subtype, would be designated A/mallard/Memphis/123/95 (H3N8). So far, no antigenic subtypes have been identified among the influenza B and C viruses. *Thogoto virus* and *Dhori virus* do not cross-react antigenically.

MORPHOLOGY AND STRUCTURE

All influenza viruses have a segmented negative-sense RNA core surrounded by a lipid envelope (Figure 2). The A and B types are distinguished by two integral membrane glycoproteins, HA and NA, that protrude from the virion surface. Influenza C virus, by contrast, contains only one type of membrane glycoprotein, HEF. A third transmembrane protein, encoded by the *M2* gene of influenza A viruses and the *BM2* gene of influenza B viruses, serves as an ion channel. Within the lipid envelope exists the matrix (M1) protein. The RNA segments are associated with nucleoprotein (NP) and

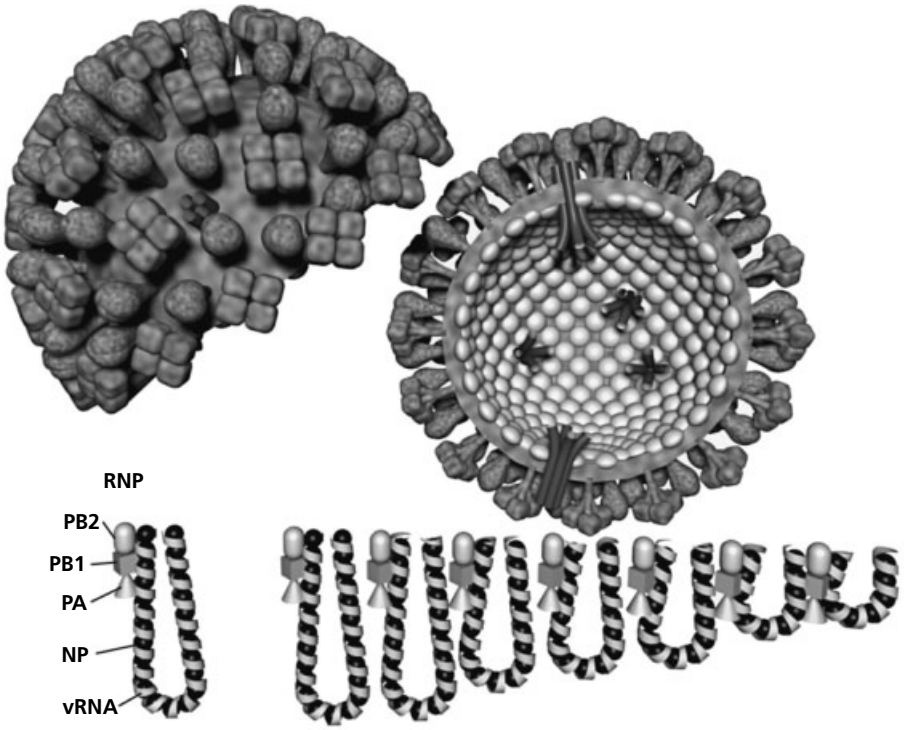

Figure 2 *Schematic diagram of an influenza A virion. The virion contains hemagglutinin (HA) and neuraminidase (NA) spikes in addition to a third membrane protein, M2. Within the viral envelope one finds ribonucleoprotein (RNP) consisting of RNA segments associated with nucleoprotein (NP), and the PA, PB1, and PB2 polymerase proteins. Three polymerase proteins are associated with the ends of vRNAs (insert). The precise location of M1 in virions is unknown, although it is associated with virion envelope, RNP, and NS2. three large polymerase proteins, designated PA, PB1, and PB2 on the basis of their overall acidic or basic amino acid composition, that are responsible for RNA replication and transcription (Krug et al. 1989).

Influenza virus particles are pleomorphic (Hoyle 1968) with spherical or filamentous morphology, or a mixture of both (Figure 3). Among clinical isolates that have undergone a limited number of passages in eggs or tissue culture, there are more filamentous than spherical particles, whereas extensively passaged laboratory strains consist almost exclusively of spherical virions (80–120 nm in diameter). Despite their distinctive shape, the filamentous virions possess many of the serological, hemagglutinating, and enzymatic characteristics of the spherical particles. The morphology of influenza virions seems to be primarily determined by the *M* gene (Bourmakina and Garcia-Sastre 2003; Roberts and Compans 1998), although both the *HA* and *NP* genes likely contribute (Jin et al. 1997; Mitnaul et al. 1996; Smirnov et al. 1991).

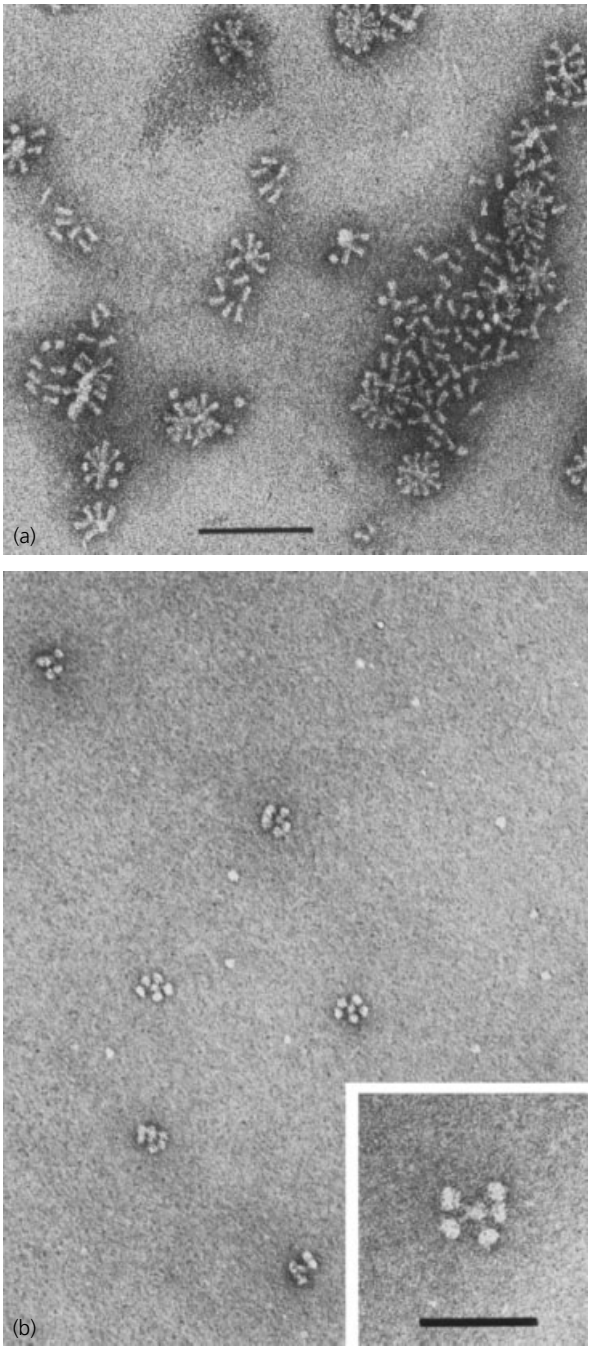

Figure 4 (a) *Hemagglutinin (HA) (bar = 100 nm) and* **(b)** *neuraminidase (NA) (bar = 50 nm) proteins isolated from detergent-disrupted virus. The molecules associate by hydrophobic C- (HA) and N- (NA) terminal sequences after the detergent has been removed. (Courtesy of Dr. K.G. Murti.) (Murti and Webster 1986).*

The HA and NA molecules that stud the surface of influenza A and B viruses range from 10 to 12 nm in length. The mean ratio of HA to NA spikes is ca. 5:1. The HA spikes are rod-shaped, whereas the NA spikes resemble mushrooms with slender stalks (Figure 4). They are not distinguishable by electron microscopy unless either the HA or NA is removed from the virion surface with a protease or rosettes of the HA and NA are formed after virions are treated with detergent. The NA distribution on virions remains uncertain. If the HA is removed with trypsin, the NA seems to be evenly distributed (Erickson and Kilbourne 1980); however, by immunoelectron microscopy with monoclonal antibodies, but not polyclonal antibodies, it seems to be clustered (Amano et al. 1992; Murti and Webster 1986). The HEF glycoproteins on influenza C viruses (8–10 nm long) are organized as hexagonal arrays of latticelike structures on the virion surface (Flewett and Apostolov 1967; Hewat et al. 1984) (Figure 5).

Within the lipid envelope, the viral RNA is associated with NP and three polymerase proteins, PA, PB1, and PB2. The organization of this ribonucleoprotein (RNP) complex within virions remains unclear. Electron microscopy has revealed helical structures in spontaneously lysed virions and in those partially disrupted with detergent (Figure 6). Similar structures can be made only with use of purified M1 protein (Ruigrok et al. 1989), indicating a significant role for this component in the generation of the RNP complex, with which M1 is known to associate (Hara et al. 2003; Kawakami and Ishihama 1983). Isolated RNP forms rod-shaped, right-handed helices that vary in length from 50 to 150 nm (Compans et al. 1972). Three-dimensional reconstitution of artificially generated viral RNPs reveal a circular shape composed of nine NP monomers, two of which form contacts with the polymerase complex (Martin-Benito et al. 2001). Each NP monomer interacts with approximately 24 nucleotides (Ortega et al. 2000) without apparent sequence specificity, and exposes the bases to the solvent (Baudin et al. 1994; Klumpp et al. 1997). The 5′ and 3′ terminal ends of viral RNA, which are complementary to each other, form a panhandle-like structure (Hsu et al. 1987).

The M1 protein is the primary determinant of virus budding (Gomez-Puertas et al. 2000; Latham and Galarza 2001) and its role in this process may be similar to that of Ebola matrix or retroviral gag proteins (Edbauer and Naso 1984; Harris et al. 1999; Jasenosky et al. 2001). Immunogold labeling with monoclonal antibodies to M1 failed to decorate the protein in virions unless they were first treated with a protease or a detergent (Murti et al. 1992). Recent cryo-electron microscopic studies suggest that M1 can modify the lipid bilayer, causing thickening of the viral envelope (Fujiyoshi et al. 1994) (see Figure 3e).

GENOME STRUCTURE AND FUNCTION

Influenza A and B viruses possess eight single-stranded RNA segments, each encoding at least one protein, whereas influenza C viruses contain only seven segments. Genome lengths differ widely among the three types of influenza viruses, some variations also being found among strains within the same type. Type B

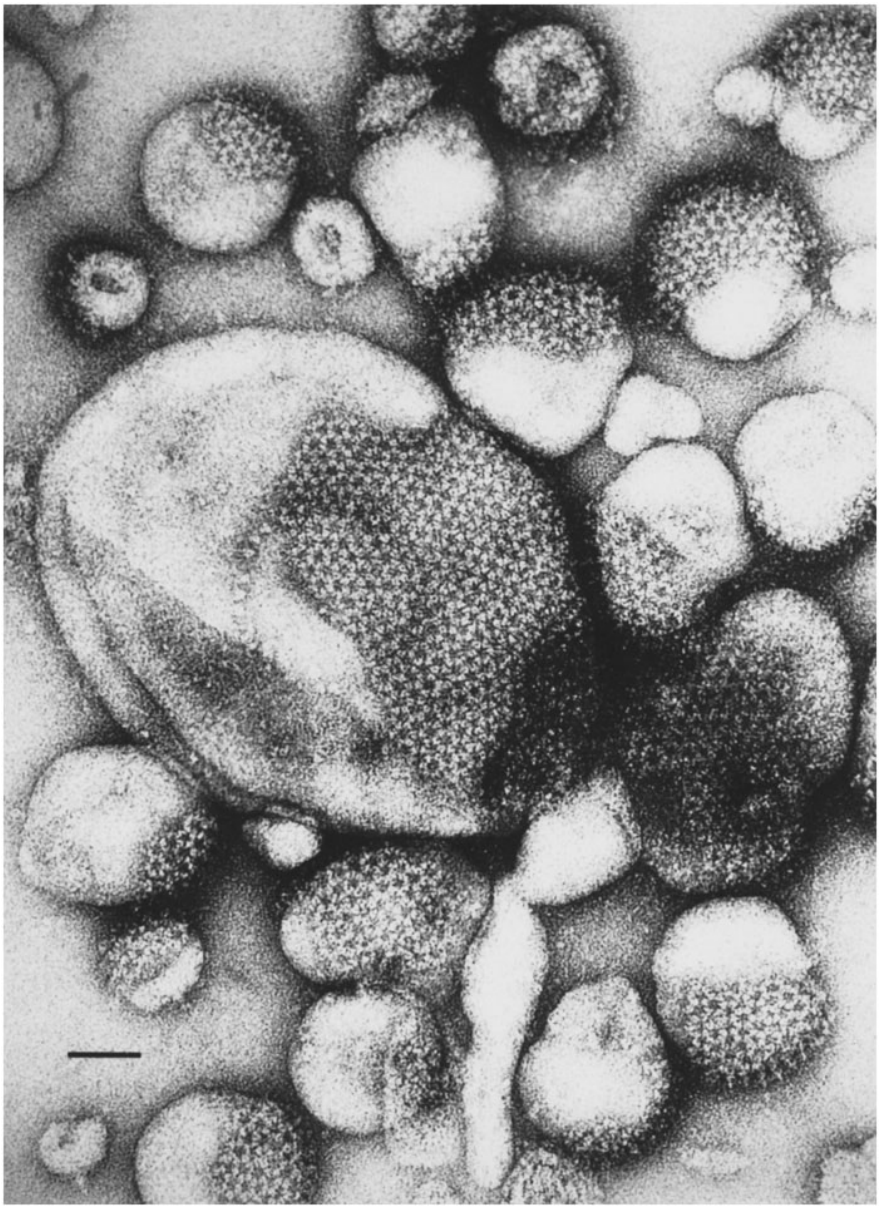

Figure 5 *Negatively stained influenza C virions with an array of extended glycoproteins. Bar = 50 nm. (Courtesy of Dr. R.W.H. Ruigrok.) (Hewat et al. 1984).*

viruses have the longest genome (ca. 14 600 nt) followed by A (ca. 13 600 nt) and then C (ca. 12 900 nt). Within each type, the lengths of genes other than the HA and NA (for A and B viruses) and the HEF (for C viruses) are highly conserved. The viral genome constitutes 2 percent of the mass of the virion.

In each of the eight RNA segments of all influenza A viruses, the first 12 nucleotides at the 3′ end and the last 13 at the 5′ end are highly conserved and contain promoter activity (Fodor et al. 1994; Fodor et al. 1995; Li and Palese 1992; Neumann and Hobom 1995; Parvin et al. 1989; Piccone et al. 1993; Seong and Brownlee 1992a; Seong and Brownlee 1992b; Yamanaka et al. 1991b) (Figure 7). Similar structures have been identified in the RNA segments of influenza B (conserved sequence: 5′ AGUAG(A/U)AACAA and 3′ UCGUCUUCGC) and C (conserved sequence: 5′ AGCAGUAGCAA and 3′ UCGU(U/C)UUCGUCC) viruses as well. The promoter regions of influenza A and B virus RNAs are interchangeable (Crescenzo-Chaigne et al. 1999; Muster et al. 1991), although the chimeric virus resulting from such modification is attenuated (Muster et al. 1991). The partially complementary 5′ and 3′ ends of the vRNA or cRNA, respectively, were thought to form a panhandle structure (Hsu et al. 1987). However, extensive characterization of promoter mutants indicated that the promoter region adopts a so-called 'corkscrew' structure characterized by intrastrand – rather than interstrand – base-pairing between the 5′ and 3′ terminal nucleotides (Flick et al. 1996; Flick and Hobom

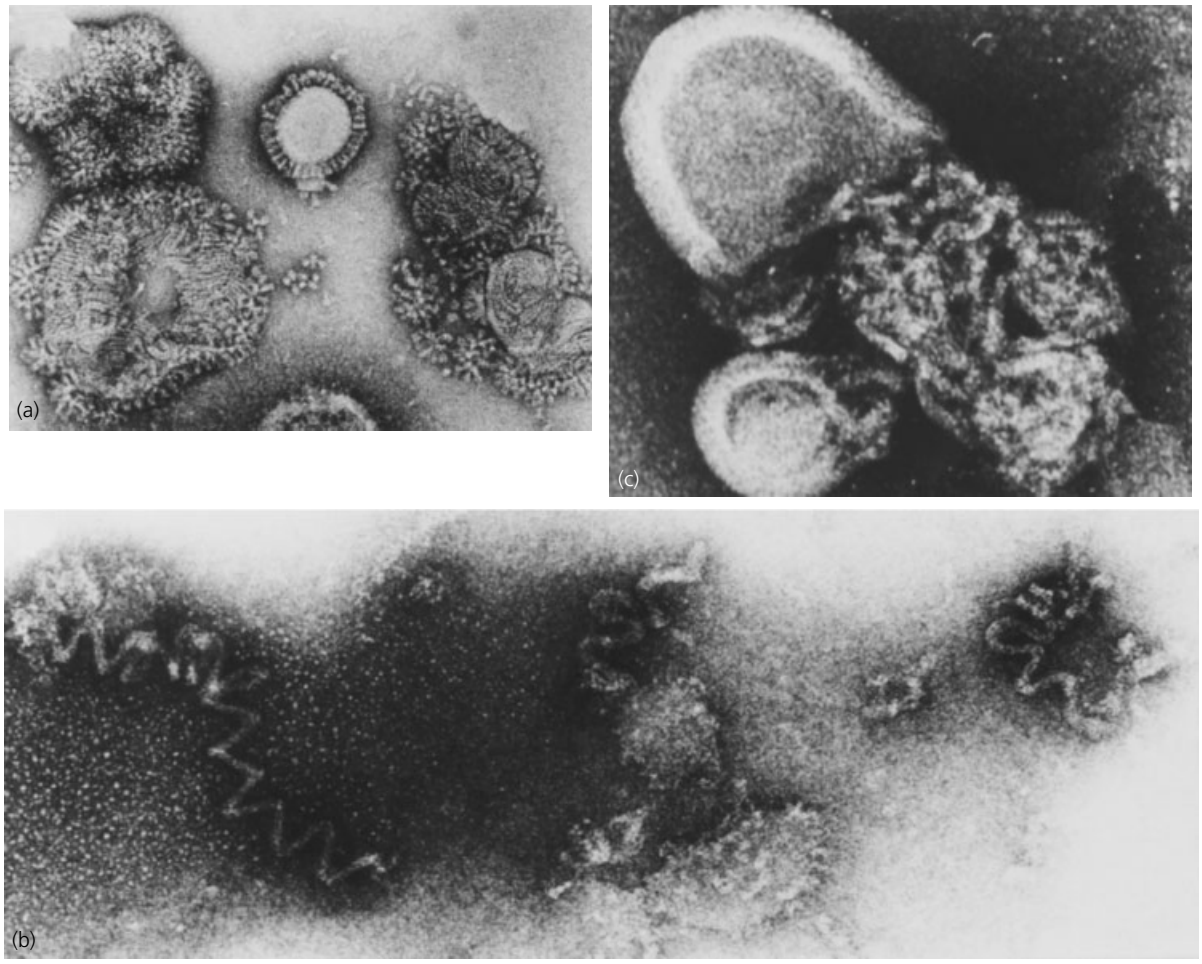

Figure 6 *Electron micrograph of the internal structure of an influenza virus.* **(a)** *Naturally disrupted virions.* **(b)** *Extended coil structures resulting from detergent treatment of virus.* **(c)** *M1 protein reconstituted into liposomes. (Courtesy of Dr. R.W.H. Ruigrok, Ruigrok et al. 1989.)*

1999). Similar promoter structures have been identified for influenza C virus (Crescenzo-Chaigne and van der Werf, 2001) and Thogotovirus (Weber et al. 1997).

Most viral genes encode a single protein (Table 2); the exceptions are the *M* and nonstructural (*NS*) genes of all influenza viruses and the *NA* gene of type B virus, that encode two proteins each (Lamb and Horvath 1991). The *NS* gene of type A virus encodes both a 26-kDa (NS1) protein translated from unspliced mRNA and a 14-kDa (NS2) protein translated from spliced mRNA (Inglis et al. 1979; Lamb and Choppin 1979) (Figure 8a), which share the same AUG initiation codon and nine subsequent amino acids. A similar protein-coding strategy is employed by the type B and C influenza viruses. Some influenza A virus *PB1* genes encode a second polypeptide, termed PB1-F2, which is encoded in the +1 reading frame (W. Chen et al. 2001) (Figure 8c).

By contrast, each type of influenza virus possesses a different mechanism for expression of *M* gene products. The *M* gene of type A viruses generates an unspliced transcript encoding the M1 protein, as well as two other alternatively spliced RNAs, designated M2 and mRNA3, which differ in their use of 5′ splice sites (Inglis and Brown 1981; Lamb et al. 1981) (Figure 8b). However, a translation product of mRNA3 has not been found in vivo. The leader sequence of the M2 mRNA contains the AUG initiation codon and codons for eight subsequent residues that are shared with the M1 protein; this region is followed by a sequence encoding 88 residues in the +1 reading frame. The nine amino acid peptide encoded by mRNA3 has not been detected in infected cells. By binding to the 5′ end of the viral M1 mRNA in a sequence-specific, cap-dependent manner, the viral polymerase complex promotes splicing at the M2 mRNA 5′ site over the mRNA3 5′ site (Shih et al. 1995). The *M* gene of influenza B viruses also encodes two proteins, M1 and BM2, which are translated via a termination-reinitiation scheme of tandem cistrons; a pentanucleotide sequence, UAAUG, contains the termination codon for the M1 and the initiation codon for the BM2 (Horvath et al. 1990) (Figure 8d). Finally, in contrast to the scheme employed by influenza A viruses, type C viruses rely on spliced transcripts to produce M1 protein

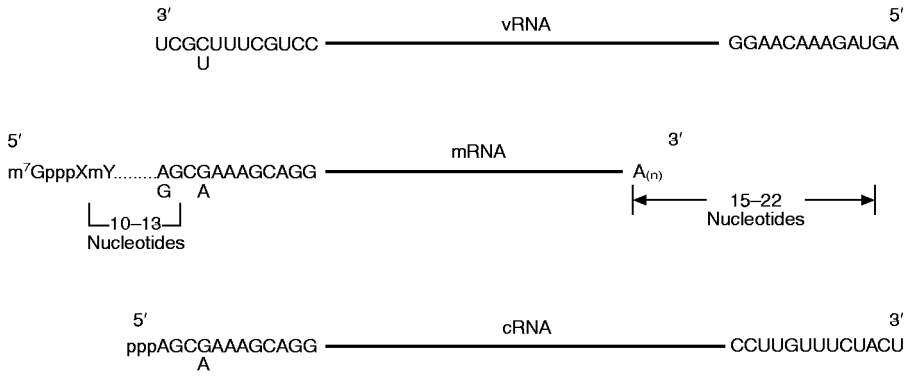

Figure 7 *Schematic diagram illustrating the differences between influenza virus virion RNA (vRNA) segments, mRNAs, and full-length cRNA (template for vRNA). The conserved 12 nucleotides at the 3′ end and 13 nucleotides at the 5′ end of each of the influenza A virus vRNA segments are indicated. Similar conserved sequences are found at the 3′ and 5′ ends of the influenza B and C virus RNA segments.*

(Yamashita et al. 1988) (Figure 8f). Splicing of the primary transcript introduces a translational termination codon, resulting in the synthesis of the M1 protein of 242 amino acids. The unspliced mRNA has the coding capacity for a 374 amino acid protein (P42) which is proteolytically cleaved to yield CM2 and M1′ (Hongo et al. 1999; Pekosz and Lamb 1998). CM2 is composed of 115 amino acids corresponding to the carboxy-terminal region of the primary transcript (Hongo et al. 1994) and has biochemical properties similar to those of the influenza A virus M2 protein (Hongo et al. 1997).

Still another mechanism of viral protein expression is represented by the influenza B virus *NA* gene, which gives rise to a bicistronic mRNA containing two initiating AUG codons that are separated by four nucleotides (Figure 8e). The 100 amino acid NB protein is translated from the 5′ AUG codon, while the 466 amino acid NA protein is translated from the second AUG codon. Even though the NA initiation codon is positioned downstream of the NB initiation site, greater amounts of NA protein (1:0.6) accumulate in cells (Williams and Lamb 1989).

Replication

The replication cycle of influenza viruses has been studied most extensively with type A strains; therefore, unless otherwise noted, the processes described below refer to viruses of that type (Figure 9).

ATTACHMENT TO UNCOATING

An influenza virus infects cells through binding of its HA or HEF protein to the cell's sialyloligosaccharide receptor. After binding, the attached virion undergoes endocytosis (White et al. 1983). The low pH of the late endocytotic vesicle triggers a conformational change in the cleavage-activated HA (Skehel et al. 1982), initiating fusion of the viral and vesicular membranes. Fusion releases the contents of the virion into the cytoplasm of the cell (uncoating). Before fusion, M2 proteins (BM2 protein for type B viruses, and possibly NB for type B viruses), by ion channeling, introduce protons into the inside of the virion, exposing the core to low pH (Hay 1992; Helenius 1992; Pinto et al. 1992; Sugrue et al. 1990b) (Figure 10). Such an event is thought to promote dissociation of the M1 from the RNP by disrupting the low pH-sensitive interaction between these molecules (Zhirnov 1990), allowing the RNP to migrate to the nucleus through the nuclear pore in an ATP-dependent manner (Kemler et al. 1994; Martin and Helenius 1991). Exposure of the viral core to low pH, however, is not required for dissociation of M1 from RNP in type C viruses (Zhirnov and Grigoriev 1994).

TRANSCRIPTION AND TRANSLATION

Once the RNP migrates into the host-cell nucleus, the associated polymerase complexes (PA, PB1, and PB2) begin primary transcription of mRNA (Krug et al. 1979), which requires cooperation with ongoing transcription by cellular RNA polymerase II. The reason for this requirement is that initiation of influenza virus mRNA synthesis depends on m^7GpppXm-containing capped primers (10–13 nt long, containing 5′-GCA-3′ at their 3′ proximal ends) that are generated from host cell RNAs by an influenza virus-encoded, cap-dependent endonuclease (Krug et al. 1989; Plotch et al. 1981). The endonuclease activity resides in the PB1 subunit (M.L. Li et al. 2001) and requires the presence of influenza viral RNA (Hagen et al. 1994); however, the requirement of both the 5′ and 3′ ends of vRNA remains controversial and may depend on the experimental parameters (Cianci et al. 1995; Li et al. 1998; Rao et al. 2003).

mRNA synthesis begins with incorporation of a G residue complementary to the penultimate C residue on the vRNAs (Beaton and Krug 1981; Kawakami and Ishihama 1983). Chain elongation is carried out by the PB1 subunit, which contains four consensus motifs for nucleic

Table 2 *Influenza A virus genome RNA and protein coding assignments*

Segment	Length (nucleotides)[a]	Encoded polypeptide	Nascent polypeptide length (amino acids)	Experimentally determined mol. wt (kDa) of polypeptides	Carbohydrates	Approx. copy no. per virion	Remarks
1	2 341	PB2	759	87	–	30–60	Component of RNA transcriptase complex
							Host-cell capped mRNA recognition and binding
2	2 341	PB1	757	96	–	30–60	Component of RNA transcriptase complex
							RNA-dependent RNA polymerase activity; capped mRNA endonuclease activity
		PB1-F2[b]	87	10.5	–	2 650	Induction of apoptosis
3	2 233	PA	716	85	–	30–60	Component of RNA transcriptase complex
							Required for replication; possible role in transcription
4	1 778	HA	566	63	+	500	Surface trimer glycoprotein
							Cleaved into HA1 and HA2
							Major antigenic determinant
							Functions in virus binding to cell surface receptors and fusion
5	1 565	NP	498	56	–	1 000	Associated with RNA segments to form ribonucleoprotein
6	1 413	NA	454	60	+	100	Surface tetramer glycoprotein; neuraminidase activity
							Functions in virus release; target of neuraminidase inhibitors
7	1 027	M1	252	27	–	3 000	Major virion component; involved in RNP transport out of nucleus
		M2	97	14	–	20–60	Coded from spliced mRNA; ion channel activity; target of adamantanes
8	890	NS1	230	26	–	NA	Nonstructural protein; inhibits mRNA transport from nucleus; interferon antagonist
		NS2(= NEP)	121	14	–	130–200	Coded from spliced mRNA; viral nuclear export protein

a) The lengths of the *HA* and *NA* genes differ among the strains.
b) Not encoded by all influenza A viruses; NA, not applicable.

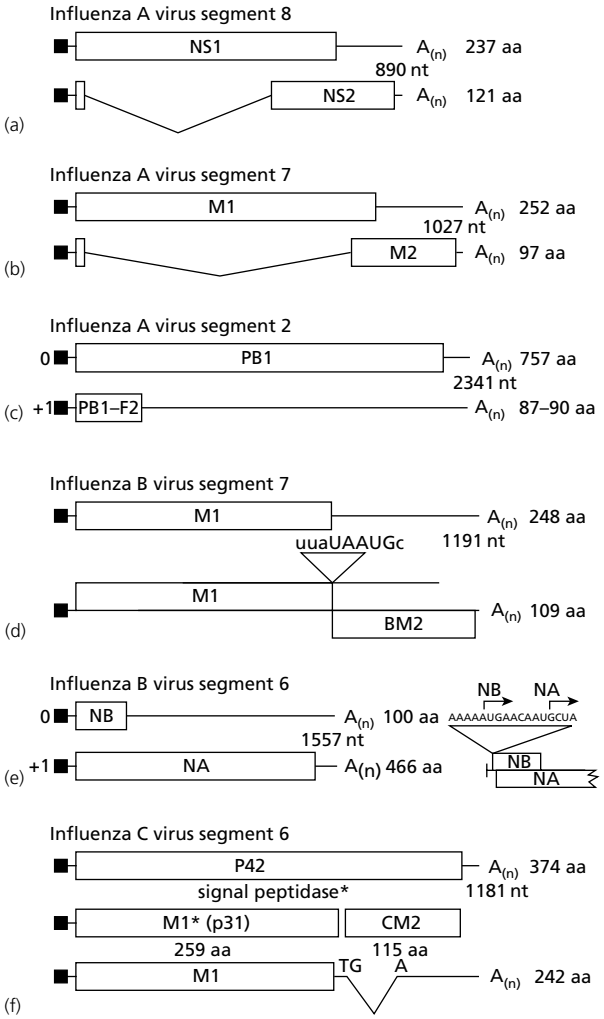

Figure 8 *Coding strategies of influenza virus genes.* **(a)** *Influenza A virus NS1 and NS2 mRNAs and their coding regions. NS1 and NS2 share ten amino-terminal residues, including the initiating methionine. The reading frame of NS2 mRNA (nucleotide positions 529–861) differs from that of NS1.* **(b)** *Influenza A virus M1 and M2 mRNAs and their coding regions. M1 and M2 share nine amino-terminal residues, including the initiating methionine; however, the reading frame of M2 mRNA (nucleotide positions 740–1 004) differs from that of M1.* **(c)** *Influenza A virus PB1 segment coding regions. Based on Kozak's rule, PB1 translation initiation may be inefficient, thereby allowing translation initiation of the PB1-F2 open reading frame by ribosomal scanning.* **(d)** *Influenza B virus RNA segment 7 open reading frames and the organization of the open reading frames used to translate the M1 and BM2 proteins. The stop–start pentanucleotide is also illustrated.* **(e)** *Open reading frames in influenza B virus RNA segment 6, illustrating the overlapping reading frames of NB and neuraminidase (NA). Nucleotide sequence surrounding the two AUG initiation codons, in mRNA sense, is shown to the right.* **(f)** *Influenza C virus mRNAs derived from RNA segment 6. The unspliced and spliced mRNAs encode P42 and M1, respectively. Cleavage of P42 by a signal peptidase yields M1′ (p31) and CM2. Thin lines at the 5′ and 3′ termini of the mRNAs represent untranslated regions. Introns in the mRNAs are shown by V-shaped lines; filled rectangles at the 5′ ends of mRNAs represent heterogeneous nucleotides derived from cellular RNAs that are covalently linked to viral sequences (Virus Taxonomy 2005).*

acid polymerases (Argos 1988; Biswas and Nayak 1994; Ishihama and Barbier 1994; Poch et al. 1989) as well as nucleotide binding sites (Asano et al. 1995; Asano and Ishihama 1997; Romanos and Hay 1984). Transcription continues until it reaches the poly(A) addition site, located 15–22 nt from the 5′ end of the vRNA. Three elements are critical for polyadenylation: a stretch of uridines near the 5′ end of the virion RNA (optimal with 5–7 residues and 16 nt from the 5′ end), which serves as the poly(A) signal (Li and Palese 1994; Luo et al. 1991; Poon et al. 1999; Zheng et al. 1999); the RNA duplex of the promoter structure; and specific nucleotides near the 5′ end of the vRNA (Pritlove et al. 1999). The current model predicts threading of the vRNA through the polymerase complex which is stably bound to the 5′ end of the vRNA throughout transcription (Fodor et al. 1994; Hagen et al. 1994). In this model, the polymerase complex bound to the promoter region would serve as a physical barrier that causes reiterative copying at the neighboring uridine stretch. The primary transcripts are then used in the production of viral proteins by the cell's cytoplasmic translation machinery. Three polymerase proteins (PA, PB1, and PB2), as well as NP, NS1, and NS2 proteins, are transported to the nucleus. The negative-strand genomic segment and the positive-strand antigenomic segments, but not viral mRNA, are coated with NP. NS1 inhibits the transport of cellular mRNA to the cytoplasm by binding to the poly(A) region (Qiu and Krug 1994) and maximizing the availability of capped primers for viral mRNA synthesis. The products of viral mRNA synthesis change as infection proceeds, indicating a temporal form of regulation (Hatada et al. 1989; Hay et al. 1977). Early in infection, the synthesis of mRNAs encoding NP and NS1 dominates; later the production of mRNAs for HA, NA, and M1 increases, while transcripts for the polymerase proteins are relatively low throughout the infection cycle, except at the earliest time. The relative amounts of mRNAs correlate with the amounts of their corresponding proteins, indicating that viral gene expression is regulated at the transcriptional level, in addition to the temporal control mechanisms governing the translational efficiency of viral mRNA (Yamanaka et al. 1988, 1991a). The production of full-length viral complementary RNA (cRNA) was believed to be delayed until viral protein had been synthesized. In this model, newly synthesized NP promoted 'read-through' of the poly(A) site, allowing the synthesis of cRNA transcripts (Beaton and Krug 1986; Shapiro and Krug 1988) which in turn serve as templates for the production of vRNA. Recent findings, however, suggest that cRNA synthesis occurs early in infection as well; at this time point, cRNA may be degraded rapidly by cellular nucleases, while increasing amounts of polymerase proteins may protect the cRNA later in infection (Vreede et al. 2004). Equimolar quantities of cRNA are synthesized throughout

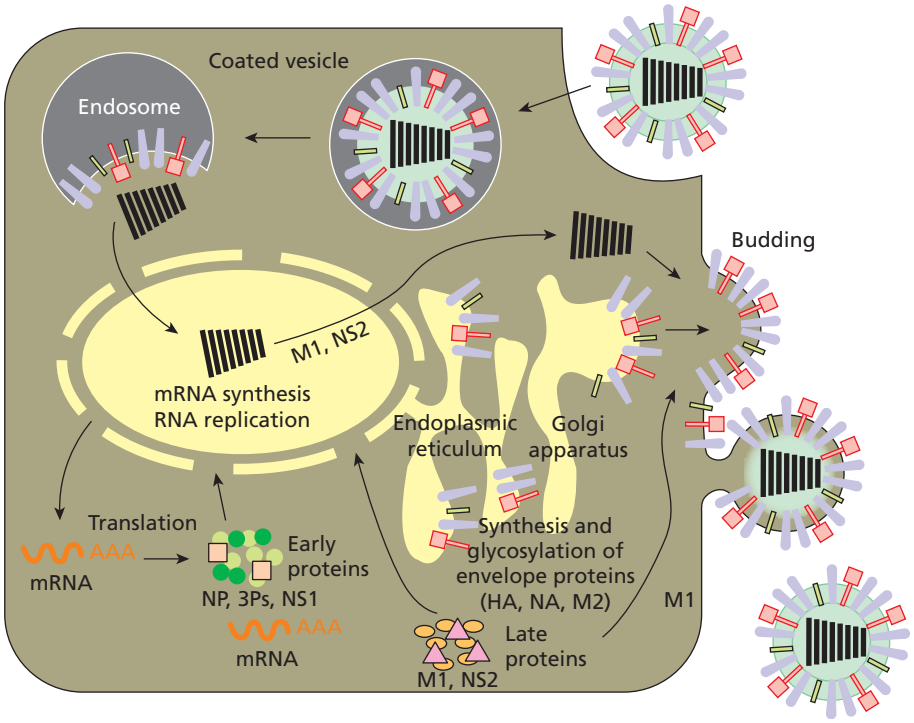

Figure 9 *Replication cycle of influenza A virus, from binding of the virus to the host cell surface to its exit from the plasma membrane. Ps, polymerase proteins. (Lamb et al. 1994.)*

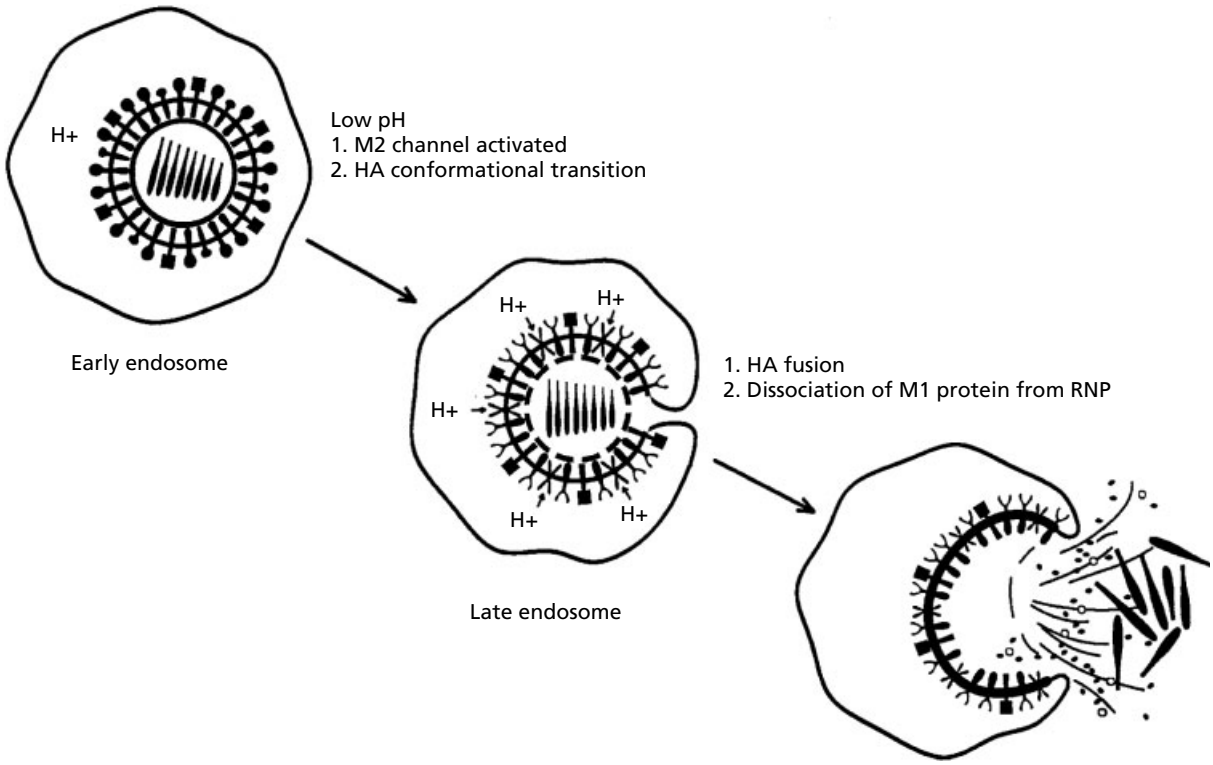

Figure 10 *Ion channel activity of the M2 protein upon virus entry. The flow of ions from the lumen of the endosome through the M2 channel into the virion interior allows the dissociation of protein–protein interactions between M1 and RNP, facilitating RNP transport to the nucleus. infection (Hay et al. 1977), indicating a lack of regulation of this process.

After their translation in the endoplasmic reticulum (ER), viral membrane proteins – HA, NA, and M2 for the type A viruses, NB for type B and HEF for type C – are translocated into the lumen of the ER, where they undergo oligomerization prior to their transport to the Golgi apparatus (Doms et al. 1993) and subsequent transport to the plasma membrane. The proteins are glycosylated in the ER (high mannose type), and then processed further in the Golgi to contain oligosaccharide of the complex type.

VIRION MORPHOGENESIS AND BUDDING

Nuclear export of vRNP complexes is mediated by the NS2 protein (Neumann et al. 2000; O'Neill et al. 1998) now also referred to as nuclear export protein (NEP), which interacts with the cellular export factor CRM1 (Neumann et al. 2000). In addition, the M1 protein is also required for nuclear export of vRNP complexes (Bui et al. 2000; Huang et al. 2001; Martin and Helenius 1991; Whittaker et al. 1995) and may execute its function by bridging viral ribonucleoprotein complexes and NS2 (NEP) (Sakaguchi et al. 2003). Electron microscopy of influenza virus-infected cells has not identified viral core structures, nor has an association of RNP with the plasma membrane been found; rather, RNP seems to associate with viral membrane proteins only when the virion is beginning to assume its shape (Patterson et al. 1988). Segment-specific virion incorporation signals have been identified on viral RNAs (Fujii et al. 2003; Watanabe et al. 2003) that promote their efficient incorporation into virions. These signals are located in the nontranslated regions at both ends of the vRNAs and extend into the translated regions, thereby conferring segment specificity. Although influenza virus can accommodate more than eight viral segments (Enami et al. 1991; Scholtissek et al. 1978b) – a finding that suggested random incorporation of vRNAs – efficient packaging relies on cis-acting signals that govern the incorporation of eight viral RNA segments into virions. The mechanism for selective vRNA virion incorporation remains to be determined. Few details of the final assembly process are known. Presumably, RNP buds outward through the cell membrane. Substantial amounts of M1 are found in the cytoplasm throughout the infection period. M1 interacts with cellular membranes (Bucher et al. 1980; Gregoriades and Frangione 1981; Hay 1974; Kretzschmar et al. 1996), and induces the formation of viruslike particles (Gomez-Puertas et al. 2000; Latham and Galarza 2001). Because at least a fraction of M1 is associated with RNP in the virion (Kawakami and Ishihama 1983; Rees and Dimmock 1981), this protein possibly serves as a molecular 'glue', interacting with RNP on the one hand and with HA, NA, or M2 on the other (Ali et al. 2000; Barman et al. 2001; Hara et al. 2003). Such interactions may function as a budding signal.

Polypeptides: nonstructural and structural

Influenza A virus comprises nine structural and one nonstructural protein (see Table 2), compared with nine structural and two nonstructural proteins in influenza B virus, and six structural and three nonstructural proteins in influenza C virus. For some influenza A viruses, an additional polypeptide is expressed from the *PB1* gene (see Table 2 and below).

POLYMERASE PROTEINS

The exact nature of the polymerase complex remains under investigation. Trimeric complexes composed of PB2, PB1, and PA are formed in virus-infected cells (Detjen et al. 1987; Honda et al. 1990; Kato et al. 1985; Kawakami and Ishihama 1983) and in transfected cells expressing all components of vRNP complexes (Digard et al. 1989; Honda et al. 2002; Hwang et al. 2000). Functional studies suggest that dimeric complexes consisting of PB1–PB2 or PB1–PA have transcriptase or replicase activity, respectively (Honda and Ishihama 1997; Honda et al. 2002; Lee et al. 2002); however, all three polymerase subunits may be required for efficient replication and transcription (Fodor et al. 2002; Perales and Ortin 1997). The polymerase complex recognizes the influenza virus promoter structure in a sequence-specific manner (Honda et al. 1987; Tiley et al. 1994) and also interacts with NP (Biswas et al. 1998). PB1 forms the structural backbone of the polymerase complex by interacting with both PB2 and PA (Honda and Ishihama 1997; Ishihama 1996; Ohtsu et al. 2002; Perez and Donis 2001; Toyoda et al. 1996). Artificially assembled vRNP complexes allowed the determination of a three-dimensional structure that revealed a compact polymerase complex with points of interaction with NP (Area et al. 2004) (Figur 11). The three polymerase proteins are highly conserved among type A viruses (Gorman et al. 1990b; Kawaoka and Webster 1989; Okazaki et al. 1989).

PB1

This protein is required for the initiation and elongation of newly synthesized viral RNA (Braam et al. 1983). Conserved PB1 residues Ser444–Asp445–Asp446 of type A viruses (443–445 for type B and 445–447 for type C), which resemble the signature sequences of other viral RNA polymerases, may form the core of the transcriptase/replicase activity (Biswas and Nayak 1994). Binding of PB1 to the viral promoter structure (Gonzalez and Ortin 1999a, b) activates the protein's capped mRNA endonuclease activity (Cianci et al. 1995; Gonzalez and Ortin 1999a, b; Li et al. 1998; M.L. Li et al. 2001; Rao et al. 2003). PB1 contains two discontinuous regions, both essential for nuclear localization (Nath and Nayak 1990).

Some influenza A virus *PB1* genes contain a second open reading frame yielding the so-called PB1-F2 polypep-

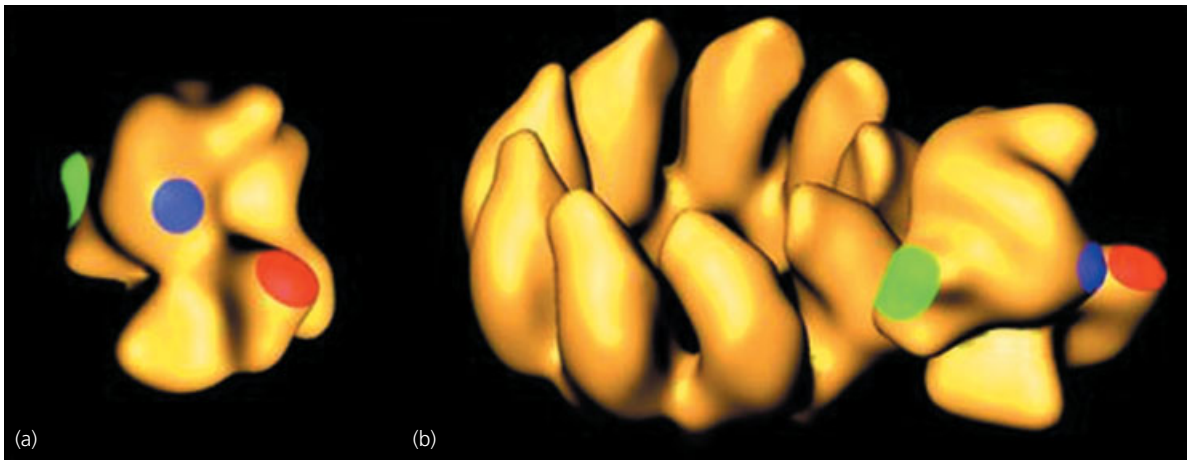

Figure 11 *Three-dimensional model for the influenza virus polymerase complex based on electron microscopic images. The colored areas depict the location of subunit domains: N-terminal region of PB2 (red), C-terminal region of PA (blue), C-terminal region of PB1 (green).* **(a)** *Polymerase model;* **(b)** *position of the polymerase subunits relative to the ringlike RNP structure. tide (W. Chen et al. 2001). The 87 amino acid peptide localizes to mitochondria where it induces apoptosis (D. Chen et al. 2001; Gibbs et al. 2003). The absence of this open reading frame from some animal (particularly swine) virus isolates leaves in question the overall contribution of this peptide to influenza virus pathogenesis.

PB2

PB2 is crucial for recognizing and binding to type I cap structures of cellular mRNAs (Blaas et al. 1982; Plotch et al. 1981; Ulmanen et al. 1983). Several amino acids/amino acid stretches at position 242–282 (Honda et al. 1999), 533–564 (M.L. Li et al. 2001), and/or 363 and 404 (Fechter et al. 2003) have been identified as critical for cap-binding. PB2 is essential for viral mRNA synthesis, although its requirement for replication remains controversial (Gastaminza et al. 2003; Nakagawa et al. 1995). Two signals mediate nuclear localization of influenza A PB2 protein, one of which is involved in PB2 perinuclear binding (Mukaigawa and Nayak 1991).

PB2 plays a role in host range restriction (Almond 1977; Subbarao et al. 1993; Yao et al. 2001). In 1997, H5N1 avian influenza viruses infected humans in Hong Kong, resulting in fatal outcomes in several individuals. Reverse genetics experiments demonstrated a critical role of amino acid 627 of PB2 for efficient replication in mice (Hatta et al. 2001); a mutation from glutamic acid (found in avian isolates at this position) to lysine (found in all human influenza viruses) enhances viral replication in mice (and likely in humans), leading to increased virulence. This finding was substantiated by the identification of the same Glu-to-Lys replacement in an H7N7 influenza virus isolated from a Dutch veterinarian who succumbed to influenza virus infection in 2003 (Fouchier et al. 2004), and in H5N1 viruses isolated from Vietnamese influenza virus victims in 2004 (K.S. Li et al. 2004). This replacement affects the level of viral RNA transcription/replication (Crescenzo-Chaigne et al. 2002; Massin et al. 2001; Naffakh et al. 2000; Shinya et al. 2004). However, in the ferret model, increased virulence has not been associated with this change (Zitzow et al. 2002) and viruses without this mutation have been isolated from severe and fatal human cases of influenza (Shaw et al. 2002; Ruben Donis unpublished).

PA

The PA protein is an essential component of the viral polymerase complex; however, its exact role in replication or transcription is less well defined than those of PB2 or PB1. PA is required for viral RNA replication (Honda and Ishihama 1997; Honda et al. 2002; Krug et al. 1989; Lee et al. 2002), possibly by acting as an elongation factor (Fodor et al. 2003) or by facilitating the binding of PB1 to viral RNA (Lee et al. 2002). It has also been implicated in transcription (Fodor et al. 2002). PA reduces the half-lives of co-expressed proteins (Sanz-Ezquerro et al. 1995, 1996) but the significance of this proteolytic activity remains obscure (Naffakh et al. 2001; Perales et al. 2000). In addition, a serine protease activity has been described for this protein (Hara et al. 2001) which is not critical for viral replication in cell culture (Fodor et al. 2002), but does support efficient viral growth (Toyoda et al. 2003). Expression of PA does not result in complete nuclear localization, which can only be achieved after coexpression of PB1 or NS1 (Nieto et al. 1992).

HEMAGGLUTININ

Encoded by the fourth largest RNA segment, the HA accounts for about 25 percent of viral protein and is distributed evenly on the surface of virions. It is responsible for the attachment and subsequent penetration of viruses into cells. The HA spikes, approximately 14 × 4 nm, protrude from the virion surface (Laver and

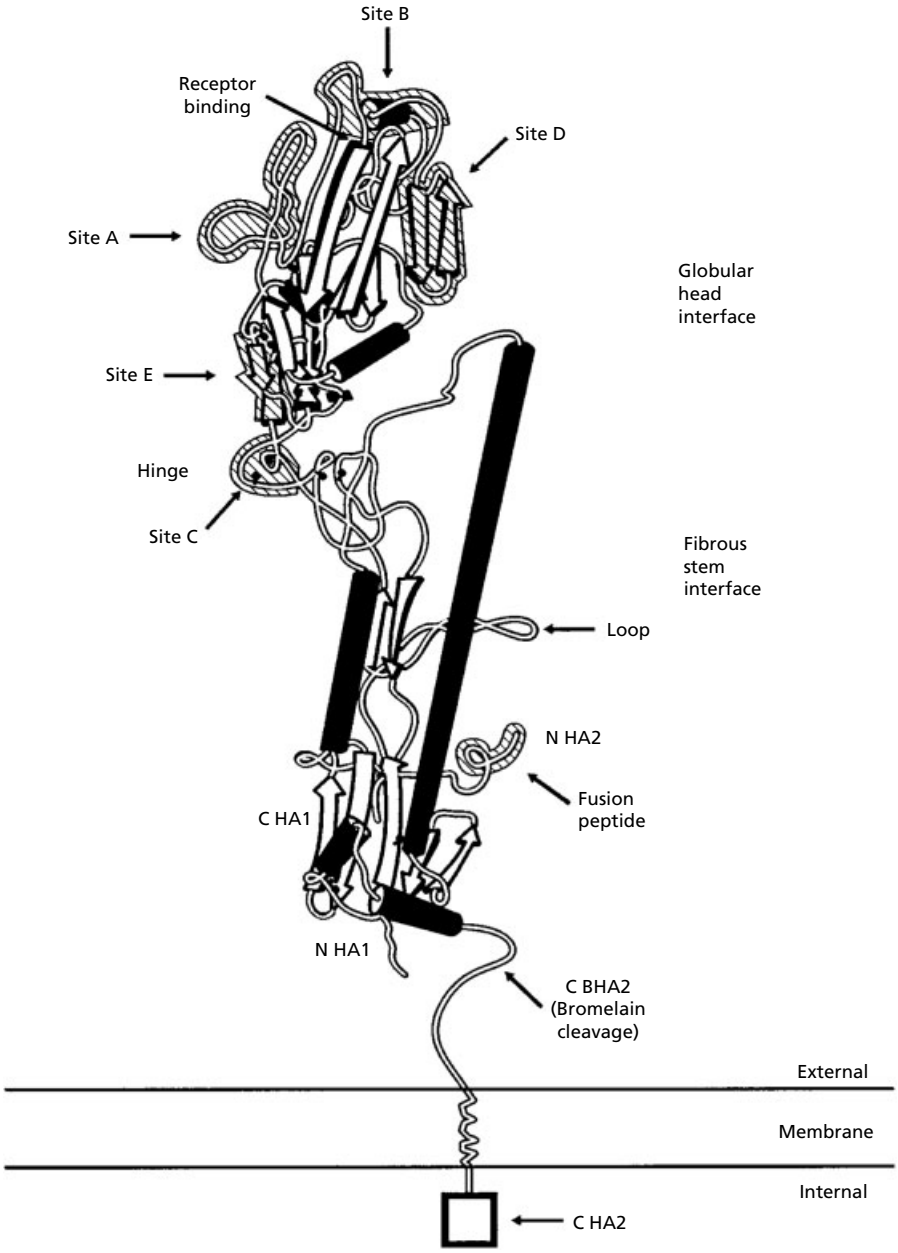

Figure 12 *Schematic diagram of the Hong Kong hemagglutinin (HA) monomer, showing folding of the HA1 and HA2 polypeptides. The shaded areas show the putative locations of the five independent antigenic areas (sites A–E). Note that the fusion peptide is also buried in the intact molecule and is exposed only after a conformational change at low pH (Bullough et al. 1994; Wilson et al. 1981).*

Valentine 1969) (Figure 12, and see Figure 3). The HA homotrimer (Wiley et al. 1977) is synthesized as a single polypeptide chain (HA0) that undergoes post-translational cleavage by cellular proteases (Klenk et al. 1975; Lazarowitz and Choppin 1975). The resulting HA1 and HA2 subunits (36 and 27 kDa) are covalently attached by a disulfide bond, while the 'two-chain' monomers are associated noncovalently to form trimers. An N-terminal signal sequence is removed. HA cleavage is required for infectivity (Klenk et al. 1975; Lazarowitz and Choppin 1975) to expose the hydrophobic amino terminus of HA2, which mediates fusion between the viral envelope and the endosomal membrane (White 1992).

Three-dimensional structure

For the ectodomain of human H3N2 virus, X-ray crystallographic structures have been determined for three different conformations: Bromelain-cleaved soluble HA (BHA) of A/Aichi/2/68(H3N2) (Wiley et al. 1981; Wilson et al. 1981; Wilson and Cox 1990) which represents the conformation of cleaved HA, the uncleaved HA0 precursor (Chen et al. 1998), and fragments of low pH-treated BHA (Bizebard et al. 1995; Bullough et al. 1994). Furthermore, the HA structures of the 1918 pandemic virus (Stevens et al. 2004), of H3 and H5 avian viruses, and an H9 swine virus have been deter-

mined (Ha et al. 2001; Ha et al. 2003). The BHA is 13.5 nm long and 1.4–4 nm in triangular cross-section, and contains all of the HA1 and the first 175 of the 221 amino acids of the HA2 subunit; it lacks only the hydrophobic membrane-anchoring peptide (Brand and Skehel 1972). The HA is folded into two structurally distinct domains, a globular head and a fibrous stalk. The globular head is entirely composed of HA1 residues and contains an eight-stranded antiparallel β-sheet. This framework supports the receptor-binding site, which is surrounded by highly variable antigenic loop structures. The fibrous stalk region, more proximal to the viral membrane, consists of residues from both HA1 and HA2. The cleavage site between HA1 and HA2 is located in the middle of the stalk. The trimeric structure is principally stabilized by the fibrous stem regions with a rather loose association of the globular heads. HA0 and cleaved HA1+HA2 are superimposable except for the region spanning the cleavage site. In uncleaved HA, the cleavage site forms a prominent surface loop in the middle of the stalk. A cavity is located next to the cleavage site that is partially filled by the carboxy terminus of HA1. Upon cleavage, the carboxy terminus of HA1 becomes exposed on the trimer surface, ca. 2.2 nm from the terminus of HA2, indicating significant rearrangement and conformational change after cleavage of the HA0. The hydrophobic amino terminus of the HA2 (fusion peptide) becomes buried in the trimeric structure, filling the cavity. The cleaved HA is presumed to be metastable.

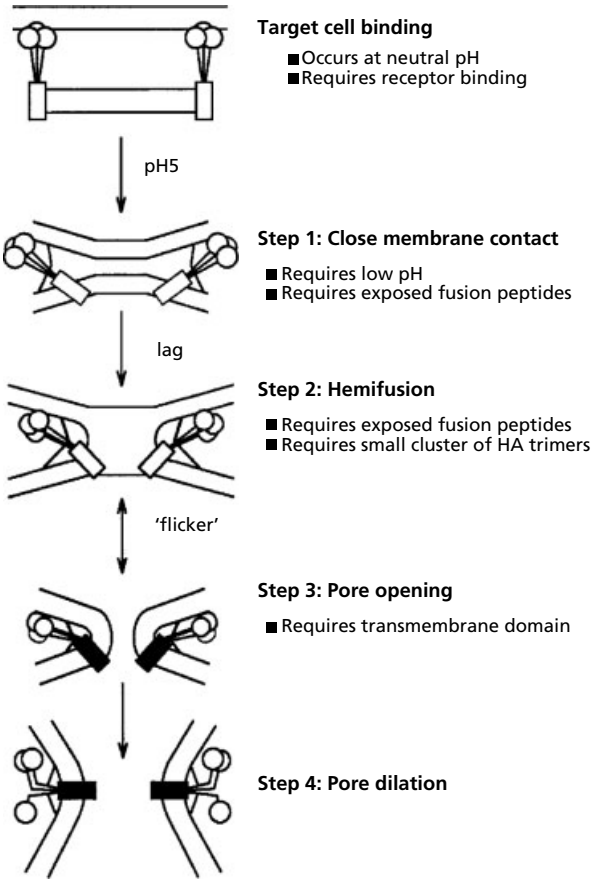

Figure 13 *Steps in HA-mediated membrane fusion. Processes described in the diagram occur after virus attachment to a cell membrane (White 1994).*

Fusion

The fusion of influenza viruses to the endosomal membrane is mediated by the HA (White 1992) (Figures 13 and 14). Under conditions of neutral pH, the fusion peptide, which forms a small part of the amino terminus of the HA2, is located in the fibrous stem of the molecule (ca. 3.5 nm away from the viral membrane and, hence, 10 nm from the target endosomal membrane), and is well integrated into the subunit interface by a network of hydrogen bonds. The importance of the peptide in HA-mediated fusion is evident from the ability of mutations in this region that alter (Daniels et al. 1987) or abolish (Gething et al. 1986b) fusion activity. When the pH is ca. 5 (late endosomal pH), the tertiary structure of the HA is altered (Skehel et al. 1982; White and Wilson 1987) (Figure 14). This change is critical for fusion of the viral and endosomal membranes (Skehel et al. 1982; Stegmann et al. 1990; White and Wilson 1987). The three-dimensional structure of the HA1 globular head remains largely unaltered (Bizebard et al. 1995), although partial dissociation of the globular heads may occur (Godley et al. 1992). By contrast, HA2 undergoes a refolding event in which the fusion peptide is relocated more than 100 Å toward the target membrane. At neutral pH, HA2 amino acid residues 38 to 55 form a short α-helix, followed by an extended loop (residues 56–75) and a long α-helix (residues 76–126) (Wilson et al. 1981). By contrast, the X-ray crystallographic structure of proteolytic fragments of the low pH-induced form of HA2 (Bullough et al. 1994; Carr and Kim 1993; Chen et al. 1999b) reveals a triple stranded α-helical coiled-coil formed by residues 40–105. Residues 106 to 112 form a loop that connects to a shorter α-helix (residues 113 to 129) that runs antiparallel to the long α-helix. The amino- and carboxy-terminal amino acids of HA2 are connected through numerous interactions that hold these residues in place at the 'tip' of the structure. The conformational states of the HA after exposure to low pH may differ among different subtypes of the molecules (Melikyan et al. 1999; Puri et al. 1990).

The exact mechanism of membrane fusion is the subject of intensive investigation and is currently believed to involve the following steps (discussed in detail in Bentz and Mittal (2003), Skehel and Wiley (2000), and Stegmann (2000), (Figure 13). Fusion is initiated by low pH that triggers a conformational change to expose the fusion peptide, which becomes inserted into the target membrane. Next, the outer leaf-

In* **(b)** *and* **(c)***, the helices/coils shown in red (amino acids 38–55), blue (amino acids 56–75), green (residues 106–129), and dark gray (amino acids 130–175) undergo a conformational change upon exposure to low pH, while amino acids 76–105 (yellow) maintain their conformation. In* **(b)***, the fusion peptides of the individual monomers are depicted in magenta (courtesy of Dr. I. Bahar) (Isin et al. 2002).*

lets of the membrane bilayer fuse (hemifusion), followed by fusion of the inner monolayer. Further observations suggest that oligosaccharides in the stem stabilize HA in a conformation prone to undergo structural changes that are necessary for fusion (Ohuchi et al. 1997). The length of the HA cytoplasmic tail affects fusion activity (Ohuchi et al. 1998) and the transmembrane region of HA has an important, though still undefined, role in the fusion process, as glycosylphosphatidylinositol-anchored HA is impaired in its ability to form pores (Armstrong et al. 2000; Kemble et al. 1994; Markosyan et al. 2000; Nussler et al. 1997).

Folding, assembly, and intracellular transport

During its synthesis in the ER, the HA interacts transiently with the BiP/GRP78 protein (Gething et al. 1986a; Hurtley et al. 1989) and calnexin (Chen et al. 1995; Hammond et al. 1994) before acquiring high mannose-type oligosaccharide and forming trimers, a prerequisite for its transport out of the ER (Doms et al. 1993). Through interaction with *N*-linked glycans in the HA, lectin chaperones such as calnexin and calreticulin regulate and facilitate HA folding (Daniels et al. 2003). Cysteine residues in the ectodomain are essential both for efficient folding and for stabilization of the folded molecule (Segal et al. 1992). Disulfide bond formation occurs co-translationally. In the Golgi apparatus, the oligosaccharides of the HA are further processed to the complex type. The HAs of virulent avian H5 and H7 viruses are cleaved in the trans-Golgi or trans-Golgi network by ubiquitous proteases (see below). In polarized cells, the final step of HA maturation is transport to the apical cell surface (Roth et al. 1983); its transport from the trans-Golgi network is energy-dependent (Gravotta et al. 1990). The proteolipid MAL, a non-glycosylated integral membrane protein that is a component of the apical transport pathway, is required for HA apical transport (Puertollano et al. 1999). Signals responsible for apical transport reside in the transmembrane and/or cytoplasmic domains (Brewer and Roth 1991; Lin et al. 1998). The generation of basolateral-sorting signals in the HA cytoplasmic tail directed 50–60 percent of the mutant HAs to the basolateral membrane; however, the mutant virus budded almost exclusively from the apical surface, indicating that factors other than the HA-sorting signal contribute to virus budding (Barman et al. 2003; Mora et al. 2002). The transmembrane and cytoplasmic domains contain signals for specific incorporation of the HA into virions in studies with a complementation assay (Naim and Roth 1993), although an HA tail-less mutant replicated almost as well as its parent (Jin et al. 1994).

Lipid rafts are sphingomyelin- and cholesterol-enriched microdomains in the cellular membrane. They are believed to provide platforms for the assembly and budding of viruses, likely by increasing the local concentration of viral structural proteins. HA associates with rafts through its transmembrane domain (Scheiffele et al. 1997; Shvartsman et al. 2003; Takeda et al. 2003); however, deletion of the HA cytoplasmic tail affects raft association as well (Zhang et al. 2000). Wild-type HA forms clusters at the surface of infected cells; by contrast, a mutant that lost the ability to associate with rafts was distributed randomly (Takeda et al. 2003). A mutant virus containing the 'nonraft' HA was characterized by reduced budding and fusion activity (Takeda et al. 2003).

HA cleavage

A link between HA cleavability and virulence is well established in avian influenza A viruses (Horimoto and Kawaoka 2001; Klenk and Rott 1988; Steinhauer et al. 1991; Webster and Rott 1987). In virulent H5 and H7 avian viruses, the HAs contain multiple basic amino acids at the cleavage site, which are cleaved intracellularly by endogenous proteases. By contrast, in avirulent avian viruses as well as non-avian influenza A viruses, with the exception of H7N7 equine viruses (Kawaoka 1991), the HAs lack a series of basic residues and are not subject to cleavage by such proteases (Bosch et al. 1979; Bosch et al. 1981). Thus, the tissue tropism of viruses may be determined by the availability of proteases responsible for the cleavage of different HAs, leading to differences in virulence.

Two groups of proteases seem to be responsible for HA cleavage. One includes enzymes recognizing a single arginine and able to cleave 'avirulent'-type HAs, such as plasmin (Lazarowitz et al. 1973), blood-clotting factor X-like protease (Gotoh et al. 1990), tryptase Clara (Kido et al. 1992), and bacterial proteases (Tashiro et al. 1987). The second group, which remains to be identified in vivo, comprises ubiquitous intracellular subtilisin-related proteases, furin, and PC6, which cleave virulent-type HAs with multiple basic residues at the cleavage site (Horimoto and Kawaoka 1994; Stieneke-Grober et al. 1992). Studies with HA cleavage mutants have demonstrated that the number of basic amino acids at the cleavage site and the presence or absence of a nearby carbohydrate affect HA cleavability by intracellular proteases in an interrelated manner (Kawaoka et al. 1984; Kawaoka and Webster 1988, 1989; Ohuchi et al. 1989; Vey et al. 1992). The proposed sequence requirement for HA cleavage by intracellular proteases, in the absence of a nearby carbohydrate (at residue 11 in H5 numbering) is Q–R/K–X–R/K–R (X = non-basic residue). If the carbohydrate moiety is present, virulence is maintained only if two basic amino acids are inserted (Q–X–X–R/K–X–R/K–R), or if the conserved glutamine at position –5 or the proline at position –6 is altered (i.e. B(X)–X(B)–R/K–X–R/K–R (B = basic residue)). In addition, the amino acid immediately downstream of the cleavage site (the amino terminal residue of the HA2) affects HA cleavage by intracellular proteases (Horimoto and Kawaoka 1995). The HA cleavage enzyme seems to be located in either the trans-Golgi or the trans-Golgi network, to be calcium-dependent, and to have an acidic pH optimum (Klenk et al. 1974, 1984; Walker et al. 1992). HA cleavage can be augmented by the ability of the A/WSN/33 (H1N1) NA protein to sequester plasminogen (Goto and Kawaoka 1998), hence increasing the local concentration of this ubiquitous protease precursor. This NA function relies on the presence of a carboxy-terminal lysine residue and the absence of an oligosaccharide side chain at position 146 (N2 numbering).

Oligosaccharide side-chains

The location and number of glycosylation sites are not conserved among HAs of different strains and subtypes (Goto and Kawaoka 1998; Nobusawa et al. 1991). Rather, these sites are scattered throughout the HA, although they tend to cluster around the antigenic sites on the globular heads. The HAs of individual virus strains contain from 5 to 11 sites, with the glycosylation sequence around residues 20–22 conserved in type A strains, except in some virulent avian strains in which the HA is cleaved by intracellular proteases (corresponding to residue 11 in the H5 numbering system; see section on HA cleavage). Some 17–20 percent of the total protein surface of the H3 HA could be covered by carbohydrate. The presence or absence of oligosaccharide side-chains in the HA (reviewed in Schulze (1997), affects antibody (Skehel et al. 1984) and $CD4^+$ T cell (Jackson et al. 1994) recognition of the molecule, calnexin/calreticulin binding (Hebert et al. 1996), receptor binding affinity and/or specificity (Gambaryan et al. 1998; Gunther et al. 1993; Matrosovich et al. 1999; Ohuchi et al. 1997; Tsuchiya et al. 2002), virulence (Hartley et al. 1997; Naeve et al. 1984), replication (Wagner et al. 2002), host range (Romanova et al. 2003), and fusion activity (Ohuchi et al. 1997). Reverse genetics studies demonstrated that growth restriction due to the lack of HA glycosylation site(s) can be partially overcome by the introduction of an NA of a different subtype (Baigent and McCauley 2001; Wagner et al. 2000), indicating that a functional balance between HA and NA is critical for efficient virus replication. Moreover, in H3 (Gallagher et al. 1992) and H7 (Roberts et al. 1993) HAs, no particular oligosaccharide side-chain is required for folding, intracellular transport or function of the molecule; however, at least two or three oligosaccharide chains (depending on the source of the HA) must be present to ensure transport of the molecule to the cell surface.

Acylation

The three cysteine residues in the carboxyl-terminal region of HA2 are acylated with palmitic (Schmidt 1982) by a thioester linkage (Veit et al. 1990). The lack of HA acylation affects HAs differently depending on the subtype. For instance, loss of palmitic acid does not impede the fusion activity of H3 (Steinhauer et al. 1991) or H7 HA (Philipp et al. 1995; Veit et al. 1991), but does affect syncytial formation of the latter (Fischer et al. 1998). An H3 virus with deletion of the HA cytoplasmic tail, which contains the acylation site, was generated by reverse genetics and replicates almost as well as its parent (Jin et al. 1994). On the other hand, a virus with a substitution at the carboxy-terminal cysteine of HA (Cys563 in WSN HA numbering) was not generated by reverse genetics, possibly because of structural constraints rather than the altered palmitylation (Zurcher et al. 1994). For H1 HA, replacement of the conserved cysteine residue did not affect hemifusion but restricted fusion pore formation, suggesting that palmitic acids facilitate the transition from hemifusion to fusion pore formation (Sakai et al. 2002). Results for the H2 HAs are more controversial. One report stresses the importance of each of the cysteine residues for fusion activity (Naeve and Williams 1990), while another indicates the absence of such an effect (Naim et al. 1992).

Receptor binding

Influenza A and B virus HAs bind to oligosaccharide-containing terminal sialic acids, including (α2,6)sialyllactose, *N*-acetylneuraminic acid-α2,6-galactose-(NeuAcα2,6Galβ1),4Glc and (α2,3)sialyllactose, NeuAcα2,3Galβ1,4Glc. Topologically, the binding site is a depression. The amino acid residues that contact the terminal sialic acids (Weis et al. 1988, 1990) are highly conserved among the different HA subtypes (Nobusawa et al. 1991). The hydroxy groups at C7 and C8 of the glycerol side-chain and the *N*-acetyl group, but not the hydroxy group of C9, are important for recognition by the HA (Kelm et al. 1992; Matrosovich et al. 1992). A second ligand-binding site, for which the affinity of sialyllactose is four times weaker than that for the primary site, has been identified in the HA (Sauter et al. 1992). The biological significance of the secondary ligand binding site is unknown.

The receptor specificity of the HA differs among influenza A viruses: most avian and equine influenza viruses bind preferentially the NeuAcα2,3Gal linkage, whereas human and classic H1N1 swine influenza viruses preferentially bind the NeuAcα2,6Gal linkage on the cell surface sialyloligosaccharides (Rogers and Paulson 1983; Rogers et al. 1983b; Rogers and D'Souza 1989). Early studies suggested that epithelial cells in human trachea contain sialic acid (SA) α2,6Gal but not SAα2,3Gal sialyloligosaccharides on the cell surface (Baum and Paulson 1990), and that virus with NeuAcα2,6Gal specificity binds epithelial cells lining human trachea, whereas those with NeuAcα2,3Gal specificity do not (Couceiro et al. 1993). Recent findings using cultures of differentiated human airway epithelial cells indicate that SAα2,6Gal sialyloligosaccharides are expressed on nonciliated epithelial cells, whereas ciliated cells (which represent a minor cell population of the epithelium) express SAα2,3Gal sialyloligosaccharides (Matrosovich et al. 2004). In accordance with this finding, human viruses infect preferentially nonciliated cells, while avian viruses infect ciliated cells. These results support recent documentation of human infection by avian viruses (Claas et al., 1998a, b; Fouchier et al. 2004; K.S. Li et al. 2004). However, it remains unknown whether the prevalence of different cell types in this in vitro system correlates with that in a natural setting (i.e. human respiratory tract). Thus, it has yet to be established whether the relative inefficiency of human infection by avian viruses (Beare and Webster 1991) is due to a limited number of cells susceptible to avian viruses in human airway or other unknown restrictions.

Epithelial cells in duck intestine (the replication site of avian influenza viruses) and those in horse trachea contain SAcα2,3Gal but not SAα2,6Gal sialyloligosaccharides (Ito et al. 1997; Ito and Kawaoka 2000). It is interesting that epithelial cells in pig trachea contain both types of sialyloligosaccharides (Ito et al. 1998) which explains why both human and avian viruses replicate efficiently in pigs (Kida et al. 1994). Thus, the receptor specificities of the viruses correspond to the presence of the receptor at the replication site of the virus (reviewed in Ito and Kawaoka (2000)). The HAs of influenza B viruses also preferentially recognize NeuAcα2,6Gal linkages (Xu et al. 1994). However, an avian H5N1 virus isolated from an individual in Hong Kong in 1997 bound to NeuAcα2,3Gal-containing receptors but not to those containing an α2,6-linkage (Matrosovich et al. 1999), indicating that receptor specificity (while being an important determinant of host range restriction) does not prohibit avian-to-human transmission.

Human H1 viruses from the 1918 and 1957 pandemic period seem to recognize both SAα2,6Gal- and SAα2,3Gal-containing receptors, while those isolated after 1977 have human-like receptor binding specificity (Rogers and D'Souza 1989). X-ray crystallographic studies of the pandemic 1918 HA (H1 subtype) and related human and swine HAs suggest that a combination of (minor) structural modifications allowed the 1918 HA to bind to human receptors, despite its avian-like amino acid sequence (Gamblin et al. 2004; Stevens et al. 2004).

In addition to the importance of linkage specificity between sialic acid and galactose (i.e. α2,3 vs α2,6 linkage), the sialic acid species (i.e. *N*-acetyl vs *N*-glycolyl sialic acid) is also involved in host range restric-

tion of influenza viruses. Influenza viruses differ in their recognition of *N*-acetyl vs *N*-glycolyl sialic acid (Higa et al. 1985); correspondingly, the prevalence of sialic acid species differs among animal species. *N*-glycolyl sialic acid linked to galactose by α2,3 linkages (NeuGcα2,3Gal) is prevalent in epithelial cells of horse trachea, allowing replication of viruses recognizing this glycoconjugate moiety but not of those recognizing *N*-acetyl sialic acid (Suzuki et al. 2000). Likewise, NeuGcα2,3Gal is a determinant of host range restriction in ducks (Ito et al. 2000).

Receptor specificity is largely determined by the nature of the amino acids at position 226 and 228. For human H2 and H3 viruses, substitution of Gln-226 with Leu and Gly-228 with Ser shifts receptor specificity from avian to human receptor binding (Connor et al. 1994; Naeve et al. 1984; Rogers et al. 1983a). Human H3 virus replication in ducks depends on the presence of avian-like amino acids at these positions (Hinshaw et al. 1983b; Naeve et al. 1983, 1984; Vines et al. 1998). In addition to these positions, substitution of residues at position 136, 190, 195, or 225, affect receptor binding affinity or specificity to various extents (Martin et al. 1998; Matrosovich et al. 2000; Nobusawa et al. 2000).

Host-cell-mediated selection of antigenic variants

The HA antigenicity of human influenza A and B viruses grown in embryonated hens' eggs differs from that of viruses isolated and passaged in a variety of cell cultures, including chicken embryo fibroblasts (Katz et al. 1987; Katz and Webster 1992; Robertson et al. 1987; Schild et al. 1983); even so, minor egg isolates contain the same antigenic phenotype as the tissue culture-grown viruses (Oxford et al. 1991). A similar phenomenon was discovered by Burnet and Clarke (1942) as 'O (as original)–D (as derived)' variation during passages of human viruses in eggs; O form virus agglutinated human or guinea-pig erythrocytes in preference to fowl erythrocytes, while D form viruses agglutinated them equally. Because tissue culture-grown viruses contain the same amino acid sequences of the HA as those replicating in humans, mutants are selected during replication in eggs (Katz et al. 1990; Rajakumar et al. 1990; Robertson et al. 1990). This finding is supported by the greater efficiency of primary isolation of human virus in cell culture than in eggs (Dumitrescu et al. 1981; Monto et al. 1981). Comparison of the HA sequence among viruses recently isolated in eggs or cell culture revealed mutations around the receptor binding pocket. Growth of human isolates in the allantois of eggs leads to the selection of receptor-binding variants (Ito et al. 1997; Mochalova et al. 2003; Smirnov et al. 2000) and results in enhanced receptor-binding affinity (Gambaryan et al. 1999). A/Hong Kong/156/97 virus grown in cell culture was significantly more pathogenic in mice than its egg-grown counterpart (Hiromoto et al. 2000); sequence analysis revealed amino acid changes in HA, PB1, PA, NP, and NS1. Inactivated vaccines prepared from tissue culture-grown viruses induce better protective immunity than do those from egg-grown viruses in animal models (Katz and Webster 1992; Newman et al. 1993; Wood et al. 1989) as well as in humans (Newman et al. 1993), although differences were not found when animals were immunized with vaccinia viruses that expressed the HAs of viruses grown in eggs or tissue culture (Rota et al. 1987, 1989).

NP

The NP (reviewed in Portela and Digard (2002)), the most abundant component of RNP, is a type-specific antigen associated with viral RNA. It covers 20–24 nucleotides (Compans et al. 1972; Duesberg 1969; Jennings et al. 1983; Ortega et al. 2000), exposing the bases to the outside and inducing melting of the secondary structure (Baudin et al. 1994; Klumpp et al. 1997). Thus, vRNA wraps around the NP scaffold. The RNA-binding region of the NP of influenza A virus has been mapped between residues 91 and 188 (Albo et al. 1995; Kobayashi et al. 1994). By electron microscopy, purified NP has a rodlike shape with dimensions of 6.2×3.5 nm and mostly exists in polymeric forms, ranging from trimers to large structures that resemble intact viral RNP (Ruigrok et al. 1989) (Figure 15). However, the formation of helical structures similar in conformation and density to intact viral RNP requires the presence of vRNA and M1 (Huang et al. 2001).

NP may undergo several stages of maturation, in which early disulfide-linked NPs are converted into disulfide-free NP which forms noncovalently stabilized oligomers (Elton et al. 1999; Prokudina et al. 2004; Zhao et al. 1998). It possesses several signals that regulate its nuclear import early in infection, but cytoplasmic accumulation late in infection (Bullido et al. 2000; Davey et al. 1985; Neumann et al. 1997; O'Neil and Palese 1995; Wang et al. 1997; Weber et al. 1998). Migration back to the cytoplasm presumably occurs as a component of RNP (Martin and Helenius 1991; Rey and Nayak 1992) and cytoplasmic accumulation requires interaction of NP with actin filaments (Digard et al. 1999). These transport processes are regulated by phosphorylation (Bui et al. 2002; Bullido et al. 2000; Neumann et al. 1997). NP also interacts with CRM1 (Elton et al. 2001), a cellular nuclear export factor; however, the significance of this finding for virus replication is not yet known. Free NP is needed for vRNA synthesis (Beaton and Krug 1986) and NP mutants have been identified that lead to defects in RNA replication, presumably by affecting the protein's ability to interact with the polymerase complex (Biswas et al. 1998; Mena et al. 1999). NP is also thought to play a role in host range restriction, as indicated by successful, host-depen-

dent rescue of the ts phenotype (Scholtissek et al. 1985) and restriction of avian–human influenza A virus reassortants for replication in primates (Clements et al. 1992; Murphy and Clements 1989; Snyder et al. 1987). This evidence notwithstanding, direct support for this role of NP is lacking.

NA

The tetrameric NA protein of influenza A viruses (Figure 16), a type II glycoprotein with its amino terminus inside the cell and its carboxyl terminus outside (Air and Laver 1989), is one of two major glycoproteins on the virus surface. It has an uncleaved amino-terminal signal/anchor domain and a six amino-acid tail (Blok and Air 1982b; Fields et al. 1981). Although the precise location of the amino-terminal six polar residues is unknown, they are presumed to be exposed to the cytoplasm. The NA has a box-shaped head ($10 \times 10 \times 6$ nm) comprising four co-planar and roughly spherical subunits and contains the enzyme-active center and major antigenic sites (Colman et al. 1983; Varghese et al. 1983) (Figure 17). The stalk is centrally attached to the head with a hydrophobic region by which the stalk is embedded in the viral membrane (Blok and Air 1982b; Fields et al. 1981). The stalk region is flexible in length and sequence. In contrast to the remainder of the NA, the six amino-acid cytoplasmic tail is highly conserved among all NA subtypes of influenza A virus (Blok and Air 1982a, b). This region is important for incorporation of the NA into virions but is not essential for virus replication (Bilsel et al. 1993; Garcia-Sastre and Palese 1995; Jin et al. 1994). Although deletion of five of these residues (leaving the initiating methionine) does not affect the viability of viruses, it causes attenuation because of the reduction in virion NA molecules. Mutant viruses lacking the NA or NA and HA cytoplasmic tails contain more filamentous than spherical particles (Jin et al. 1997; Mitnaul et al. 1996). An HA/NA-tail-less mutant had reduced vRNA-to-protein content (Zhang et al. 2000), suggesting an interaction of the NA and/or HA cytoplasmic tails with other viral or cellular components during vRNA virion incorporation and virion formation.

Reverse genetics experiments demonstrated that the NA stalk can be deleted almost completely or be extended by 58 amino acids to accommodate a variety of foreign sequences (Castrucci and Kawaoka 1993; Castrucci et al. 1994; Luo et al. 1993). In addition to laboratory isolates, avian viruses, especially those circulating in land-based birds (e.g. chickens) contain deletions in the NA stalk region (Banks et al. 2001; Bender et al. 1999; Blok and Air 1982b; Blok et al. 1982; Matrosovich et al. 1999; Spackman et al. 2003). 'Short-NA-stalk' viruses are characterized by mutations in HA1 which could affect receptor binding (Baigent and McCauley 2001; Banks et al. 2001; Bender et al. 1999; Matrosovich et al. 1999; Mitnaul et al. 2000; Spackman et al. 2003); these mutations likely compensate for a decreased ability to release viruses with shortened stalks. The occurrence of interrelated mutations indicates that the balance between HA and NA functions is critical for efficient influenza virus replication (reviewed in Wagner et al. (2002)).

A recombinant virus expressing reduced levels of NA was attenuated in mice (Solorzano et al. 2000). NA-deficient viruses, generated by repeated passage in the presence of bacterial NA and antibodies to viral NA, replicate in cell culture when a bacterial NA is added exogenously, as well as in animals (Hughes et al. 2000; Liu and Air 1993; Liu et al. 1995). These viruses possess

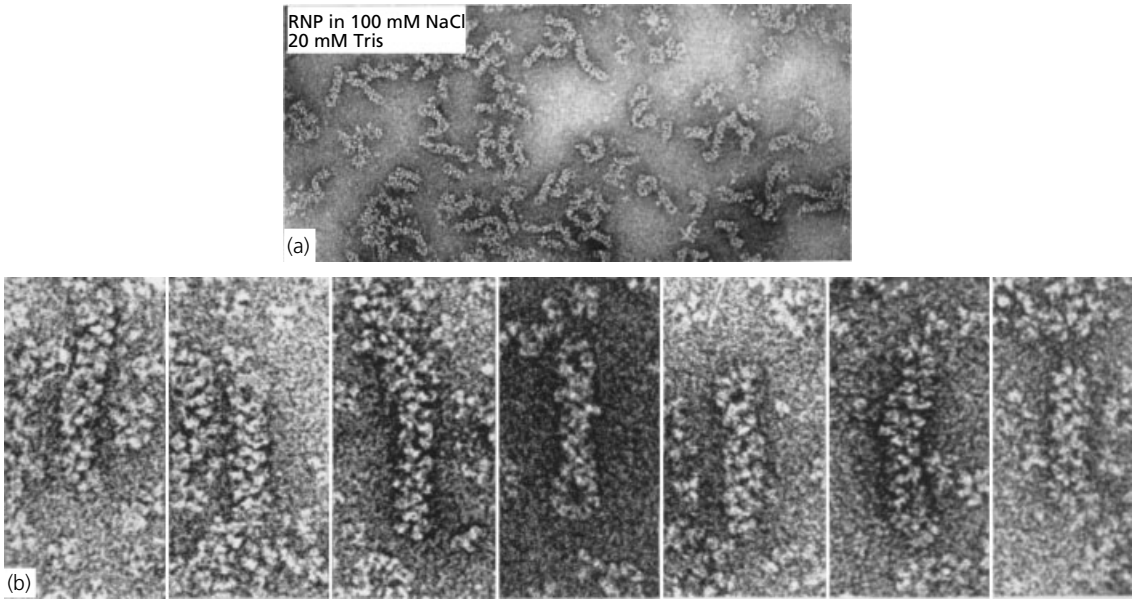

Figure 15 *Morphological features of RNP* **(a)** *and NP* **(b)**. *(Courtesy of Dr. Rob W.H. Ruigrok) (Ruigrok and Baudin 1995)*

internal deletions of 800–900 nt, leaving regions encoding the cytoplasmic and transmembrane domains and part of the stalk. Whether the truncated NA molecule exists in infected cells remains unknown. With the identification of segment-specific virion incorporation signals at the 5′ and 3′ ends of viral RNAs (Fujii et al. 2003), it seems more likely that the terminal NA sequences are maintained to ensure efficient virion incorporation. Analysis of NA-deficient viruses revealed mutations around the HA receptor-binding pocket (Hughes et al. 2000), further emphasizing the importance of a balance between HA and NA functions.

The NA plays a role in host range restriction (Hinshaw et al. 1983b). While the sialidase activity of most human and pig isolates becomes undetectable below pH 4.5, duck isolates retain their enzymatic activity under these conditions (Takahashi et al. 2001), consistent with virus propagation in the acid environment of the digestive tract. NA is also important for plaque formation by A/WSN/33(H1N1) in Madin–Darby bovine kidney (MDBK) cells and for the neurovirulence of this virus (Nakajima and Sugiura 1980; Schulman and Palese 1977; Sugiura and Ueda 1980). These phenotypes were characterized by loss of the oligosaccharide sidechain from the WSN NA, which is conserved among the NAs of all other influenza A viruses (Li et al. 1993). This observation is now explained by HA cleavage promoted by plasminogen-binding activity of WSN NA (see HA cleavage section) (Goto and Kawaoka 1998). In addition, NA seems to induce apoptosis (Mohsin et al. 2002; Morris et al. 2002), likely through the activation of transforming growth factor beta (TGF-β) (Schultz-Cherry and Hinshaw 1996), although the significance of this finding for influenza pathogenesis is not known.

Three-dimensional structure

The NA three-dimensional structure has been solved in both type A and B viruses. Despite the 28 percent homology between these two types of viruses, the overall folding patterns of their NAs are almost identical

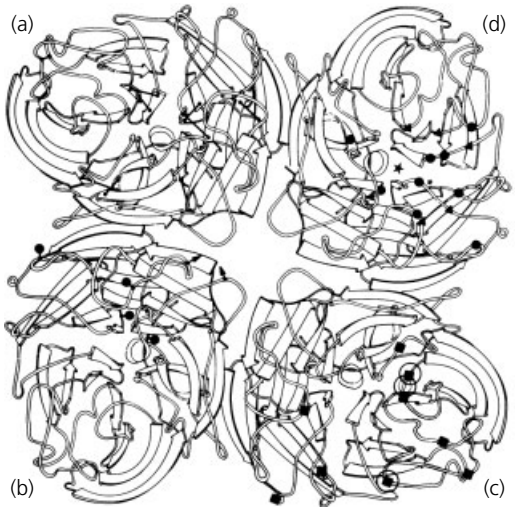

Figure 17 *Schematic illustration of the neuraminidase tetramer viewed from above, down the symmetry axis. (Burmeister et al. 1992; Colman et al. 1983; Janakiraman et al. 1994; Varghese et al. 1983), and type B NA can functionally replace the type A enzyme (Ghate and Air 1999). The tetrameric NA protein has circular four-fold symmetry stabilized by calcium. The polypeptide chain folds into six topologically identical four-stranded antiparallel β-sheets arranged like propeller blades (Figure 17). The product of catalysis, sialic acid, is bound in a large pocket on the distal surface, flanked and surrounded by nine acidic residues, six basic residues and three hydrophobic residues – each of which is strictly conserved in all known influenza viral NA sequences. Alteration of more than half of these residues results in molecules deficient in enzyme activity (Lentz et al. 1987). The three-dimensional structure of the NA led to the synthesis of a potent sialidase inhibitor, 4-guanidino-2,4-dideoxy-2,3-dehydro-*N*-acetylneuraminic acid (von Itzstein et al. 1993), which inhibits the NA activity of both type A and B viruses (inhibition constants, 10^{-9}–10^{-10} m). The structures of NA complexed with the inhibitor 2,3-didehydro-2-deoxy-n:-acetylneuraminic acid (DANA) (Smith et al. 2001) and of a mutant NA (E119G) that is resistant to the inhibitor 4-guanidino-Neu5Ac2en (4-GuDANA) (Colacino et al. 1997) have been solved. The latter structure suggests that the E119G replacement destabilizes the NA tetramer.

Sialidase activity

The NA catalyzes the cleavage of the α-ketosidic linkage between a terminal sialic acid and an adjacent sugar

residue (Gottschalk 1957). The pH optimum of the enzyme ranges from 5.8 to 6.6, with an apparent K_m of 0.4 mm with use of N-acetylneuraminyllactose (Drzeniek and Kaluza 1972; Mountford et al. 1982). Removal of sialic acid residues by the NA promotes both entry and release of virus from infected cells (Palese et al. 1974). Avian NAs cleave NeuAcα2,3Gal in preference to NeuAcα2,6Gal. For human N2 NAs, a shift from NeuAcα2,3Gal to NeuAcα2,6Gal linkages has been observed since their introduction into the human population (Baum and Paulson 1991), presumably corresponding to the preferential recognition of the latter linkages by the HA molecule. The NA substrate specificity is determined by the nature of the amino acid at position 275 (Kobasa et al. 1999). In addition to substrate specificity, the specific activity of NA is also critical for the adaptation of avian viruses to growth in humans (Kobasa et al. 2001).

Folding, assembly, and intracellular transport

Synthesized as a monomer in the ER and translocated into the lumen of that structure, the NA rapidly forms a disulfide-linked dimer, which then non-covalently associates to form a tetramer ($t_{1/2}$ ca. 1.5–2 min). After transiently associating with the BiP/GRP78 ($t_{1/2}$ ca. 5 min), the NA is transported through the Golgi apparatus, where it acquires complex carbohydrates, rendering it resistant to endo H ($t_{1/2}$ ca. 25 min), and finally to the cell surface (Hogue and Nayak 1992; Saito et al. 1994). The mature NA contains signals for apical transport in its cytoplasmic and transmembrane domains (Barman and Nayak 2000; Kundu and Nayak 1994; Zhang et al. 2000). The transmembrane domain also contains a signal for raft association which does not overlap the apical sorting signal (Barman and Nayak 2000).

HA activity

All avian virus NAs possess HA activity (Hausmann et al. 1995; Kobasa et al. 1997; Laver et al. 1984). The HA activity can be transferred to NAs lacking this activity by altering amino acid residues that are located apart from the sialidase-active site (Nuss and Air 1991), indicating discrete HA- and NA-active sites in the NA molecule. A mutant virus with an altered HA-binding site displayed a significantly reduced hemadsorption activity and a reduction in NA enzymatic activity, but was not impaired in its ability to replicate in an avian host (Kobasa et al. 1997); thus, the biological significance of the HA activity in NA remains unknown.

NB

The dimeric, type II integral membrane protein NB (Williams and Lamb 1986) is unique to type B viruses. It is abundantly expressed in infected cells and incorporated into virions (Brassard et al. 1996). NB is composed of an 18 amino acid ectodomain, a 22 amino acid transmembrane domain, and a 60 amino-acid cytoplasmic tail (Brassard et al. 1996; Williams and Lamb 1988). Structural similarity with the M2 protein and ion channel activity (Sunstrom et al. 1996) led to the speculation that NB is the equivalent of the type A M2 protein. However, reverse genetics experiments demonstrated that NB is not critical for virus replication in vitro (Hatta and Kawaoka 2003). The role of this protein in viral replication remains obscure.

M1

The most abundant virion protein and a type-specific antigen of influenza viruses, the M1 has long been thought to be located underneath and adds to the rigidity of the lipid bilayer, although direct evidence for such a role is lacking. Immunogold labeling with anti-M1 monoclonal antibodies failed to decorate the M1 in virions unless they were first treated with a protease or a detergent (Murti et al. 1992). Cryo-electron microscopic studies suggested that the M1 can modify the lipid bilayer, causing the viral envelope to thicken (Fujiyoshi et al. 1994) (see Figure 3e). M1 is the primary determinant of virus budding and assembles into viruslike particles that are released into the medium (Gomez-Puertas et al. 2000). Furthermore, it determines the morphology of influenza virions (Bourmakina and Garcia-Sastre 2003; Roberts and Compans 1998), although other gene products may contribute (Jin et al. 1997; Mitnaul et al. 1996; Smirnov et al. 1991). Crystal structures of the N-terminal domain (amino acids 1–162) at neutral or acidic pH show a long ribbon of stacked dimers at neutral pH, while dimers were rotated in relation to each other at acidic pH (Harris et al. 2001; Sha and Luo 1997).

Located in both the nucleus and the cytoplasm (Patterson et al. 1988; Smith et al. 1987), this protein contains a karyophilic signal at residues 101–105 (RKLKR) (Ye et al. 1995). Depending on the nature of the replacement, mutations in this region have different outcomes on virus replication (Hui et al. 2003; Liu and Ye 2002). Replacement of residues 100–104 with the 'late domain' motifs PTAP or YPDL yielded virus with wild-type phenotypes (Hui et al. 2003), suggesting that this region of M1 may have a function similar to the late domains of Ebola virus or retrovirus matrix proteins. Structural similarities between M1 and human immunodeficiency virus (HIV) matrix and capsid proteins substantiate this assumption (Harris et al. 1999). In accordance with its proposed role, M1 has multiple lipid-binding regions (Bucher et al. 1980; Gregoriades and Frangione 1981; Hay 1974; Kretzschmar et al. 1996). In the cytoplasm, it is associated with cytoskeletal elements (Avalos et al. 1997).

M1 is required for nuclear export of vRNP complexes (Huang et al. 2001; Martin and Helenius 1991;

Whittaker et al. 1995), a function that relies on the association of M1 with vRNP complexes (Sakaguchi et al. 2003). M1 may therefore bridge the viral nuclear export factor NS2(NEP) and components of vRNP complexes such as PA (Hara et al. 2003).

The M1 proteins of influenza A and B viruses have a 'zinc finger' motif (Wakefield and Brownlee 1989), and purified virions contain zinc (Elster et al. 1994); however, the amount of zinc is not correlated with the RNA-binding activity of the protein and replacement of the conserved cysteine and histidine residues in the zinc finger motif did not significantly impair virus replication in cell culture (Hui et al. 2003; Liu and Ye 2002). Although serine residues between amino acids 108 and 126 of A/WSN/33(H1N1) M1 are phosphorylated (Gregoriades et al. 1990), the role of this property in viral replication is unknown; it may be important for viral replication involving intracellular movement of the protein (Whittaker et al. 1995). The influenza B M1 protein is also phosphorylated. M1 also inhibits RNP transcription activity (Perez and Donis 1998; Ye et al. 1989; Zvonarjev and Ghendon 1980), and thus is considered to serve as a molecular switch that initiates the final step of virus assembly. Furthermore, M1 contains RNA-binding domains (Eister et al. 1997; Ye et al. 1989, 1999), which have been mapped between residues 90–109 and 129–164.

One of the *M* gene products (most likely M1) contributes to the dominance phenotype shown by cold-adapted A/Ann Arbor/6/60(H2N2) in coinfection studies with other strains, both in vitro and in vivo (Whitaker-Dowling et al. 1990, 1991; Youngner et al. 1994). M1 may also be linked to rapid virus growth (Baez et al. 1980; Yasuda et al. 1994), presumably defined by the strength of its association with vRNP complexes (Liu and Ye 2002).

M2

The integral homotetrameric M2 membrane protein (Holsinger and Lamb 1991; Lamb et al. 1985; Panayotov and Schlesinger 1992; Sugrue and Hay 1991), abundantly expressed at the surface of virus-infected cells, is, nevertheless, a relatively minor component of virions (Zebedee and Lamb 1988). Sharing eight amino-terminal residues with M1, the M2 protein comprises 97 amino acids: 24 as the ecto-, 19 as the transmembrane, and 54 as the cytoplasmic domain. M2 functions as a pH-activated ion channel that permits protons to enter the virion during uncoating (Pinto et al. 1992; Sugrue et al. 1990b) and that modulates the pH of intracellular compartments, an essential function for the prevention of acid-induced conformational changes of intracellularly cleaved HAs (H5 and H7 HA subtypes of virulent avian influenza A virus) in the trans-Golgi network (Ohuchi et al. 1994; Sugrue et al. 1990b; Takeuchi and Lamb 1994). Both the imidazole ring of His-37 and the indole moiety of Trp-41 are critical for the activation and regulation of the ion channel (Okada et al. 2001; Smondyrev and Voth 2002; Tang et al. 2002; Zhong et al. 2000). The activity of the M2 ion channel is blocked by the anti-influenza drug amantadine hydrochloride (see Chemotherapy section). The M2-associated ion channel activity resides in the transmembrane region (Duff and Ashley 1992), the primary site of mutations (residues 27, 30, 31, and 34) in amantadine-resistant mutants (Hay et al. 1985). Amantadine presumably blocks the ion channel activity of M2 by steric hindrance, resulting from insertion of the active drug between Val-27 and Ser-31 of the M2 molecule (Duff et al. 1994). Reverse genetics allowed for testing of viruses with mutations or deletions in the transmembrane region of M2 (Takeda et al. 2002; Watabe et al. 2001). While such viruses are viable, they are impaired in their growth. These findings indicate that influenza A virus can undergo limited replication in cell culture without M2 ion channel activity; this activity, however, is required for efficient viral replication.

The functional role of the M2 cytoplasmic region, the longest among the influenza viral membrane proteins, is unknown but is important for virus replication (Castrucci and Kawaoka 1995). M2 co-precipitates with the RNP core prepared from purified virus (Bron et al. 1993), indicating its high affinity for this protein, a property that presumably involves the M2 cytoplasmic tail. The M2 protein forms a homotetramer by non-covalent association of M2 dimers disulfide-linked at Cys-17 or -19, or both (Holsinger and Lamb 1991; Panayotov and Schlesinger 1992; Sugrue and Hay 1991). None of the cysteine residues in the M2 is essential for viral replication (Castrucci et al. 1997), although disulfide bond formation stabilizes the M2 tetramer (Holsinger and Lamb 1991). M2 proteins are palmitylated at Cys-50 with the exception of those in H3N8 equine viruses, but are not essential for virus replication (Sugrue et al. 1990b; Veit et al. 1991). The protein is also phosphorylated, mainly at Ser-64 (85 percent), but also at Ser-82, -89, and -93 (Holsinger et al. 1995); however, replacement of Ser-64 did not affect virus replication in vitro or in vivo (Thomas et al. 1998). The M2 ectodomain may play a role in virion incorporation (Park et al. 1998).

OTHER *M* GENE PRODUCTS OF TYPE B AND C VIRUSES

BM2, encoded by the *M* gene of type B virus (Horvath et al. 1990), is expressed in large amounts late in infection and has been detected in virions (Odagiri et al. 1999). It has no obvious structural similarities with type A M2 protein (Briedis et al. 1982); however, it is an oligomeric – most likely tetrameric – integral membrane protein, and its transmembrane domain contains histidine and tryptophane residues at the same relative location and spacing as those critical for the ion channel activity of type A M2 protein (Paterson et al. 2003). In fact, BM2 possesses ion channel activity and prevents

co-expressed HA from adopting the low pH-induced conformation during transport to the cell surface (Horvath et al. 1990). These findings, together with reverse genetics studies demonstrating that BM2 is critical for the viral life cycle (Hatta et al. 2004; Jackson et al. 2004), indicate that BM2 is the equivalent of the type A M2 protein.

CM2, which resides in infected cells (Hongo et al. 1994), is generated by proteolytical cleavage of a precursor protein translated from unspliced transcripts of the *M* gene (Hongo et al. 1999; Pekosz and Lamb 1998). It is composed of 115 amino acids corresponding to the carboxy-terminal region of the precursor protein and has biochemical properties similar to the influenza A virus M2 protein (Paterson et al. 2003; Pekosz and Lamb 1997). The protein is palmitylated and phosphorylated, and the latter modification seems to accelerate tetramer formation (Z.N. Li et al. 2001; Tada et al. 1998). While these findings suggest a role of CM2 as the type C ion channel protein, direct experimental evidence is missing.

NS1

The only nonstructural protein of influenza A virus, NS1 is made in abundance during early infection. It is encoded by a co-linear mRNA, consists of 202–238 amino acids, is phosphorylated (Pekosz and Lamb 1998), and contains two karyophilic signals (Greenspan et al. 1988) as well as a latent nuclear export signal (Li et al. 1998).

The major function of NS1 is the inhibition of the cellular, anti-viral interferon (IFN) response (Garcia-Sastre et al. 1998) (reviewed in Garcia-Sastre (2001) and Katze et al. (2002)) to ensure efficient viral replication in IFN-competent hosts. In virus-infected cells, double-stranded RNA (dsRNA) is believed to trigger the activation of transcription factors such as ATF-2/c-Jun, NF-κB, or IFN-regulatory factors (IRF) that regulate IFN-β production. Similarly, IFN-α is also induced in response to virus infection. IFN induces the phosphorylation of STAT1 and STAT2, which, after dimerization and recruitment of IRF-9, activate the transcription of IFN-stimulated genes (ISG). ISGs comprise a large number of genes that establish an antiviral state in cells, including those encoding dsRNA-activated protein kinase (PKR) (PKR), Mx proteins, or proteins responsible for mRNA degradation such as 2′–5′-oligoadenylate synthetase (OAS) and RNase L. NS1 seems to interfere with these pathways by inhibiting the activation of transcription factors (Ludwig et al. 2002; Smith et al. 2001; Talon et al. 2000; Wang et al. 2000) and PKR (Bergmann et al. 2000; Hatada et al. 1999; Lu et al. 1995). It may execute its function by binding to dsRNA; however, direct protein–protein interactions between NS1 and components of the IFN system cannot be ruled out. The H5N1 avian viruses isolated in Hong Kong in 1997 induce high levels of proinflammatory cytokines, particularly tumor necrosis factor (TNF)-α and IFN-β (Cheung et al. 2002), while being resistant to the antiviral effects of these cytokines (Seo et al. 2002). These properties have been linked to the *NS* gene or NS1 protein, respectively, further emphasizing the protein's contribution to virulence (Cheung et al. 2002; Seo et al. 2002).

Besides its role in the regulation of the cellular IFN response, NS1 acts as a post-transcriptional regulator by inhibiting mRNA splicing and the nuclear export of cellular mRNA (Alonso-Caplen et al. 1992; Chen and Krug 2000; Krug et al. 2003; Lu et al. 1994; Qian et al. 1994), thereby maximizing the availability of substrate for capped primers and promoting viral mRNA synthesis. Interaction of NS1 and the cellular poly(A)-binding protein II (PABII) with the 30-kd subunit of cleavage and polyadenylation specificity factor (CPSF) blocks the binding of this protein to the AAUAAA sequence of some cellular pre-mRNAs, hence inhibiting their polyadenylation (Nemeroff et al. 1998). For some cellular mRNAs, short poly(A)-stretches have been detected whose elongation is blocked by the interaction of NS1 with PABII (Chen et al. 1999a). Both species – non-polyadenylated mRNAs and mRNAs with short poly(A) tails – remain in the nucleus where they become substrates for the endonucleolytic activity of the polymerase complex. In vitro, inhibition of splicing of mRNAs is mediated by binding of NS1 to a stem-bulge in U6snRNA (Wang and Krug 1998), which plays a critical role in the assembly/activity of spliceosomes. By contrast, in vivo, inhibition of splicing is brought about by binding of NS1 to the 30-kd subunit of CPSF (Y. Li et al. 2001). The interaction of NS1 with the 30-kd subunit of CPSF also induces the transcription of antiviral genes in an IFN-independent manner (Kim et al. 2002; Noah et al. 2003).

Two functional domains have been identified for NS1. The amino-terminal 73 amino acids constitute the RNA-binding domain and are sufficient for dimerization, as shown by structural analysis and experimental findings (Chien et al. 1997; Liu et al. 1997; Wang et al. 1999). Although mutational analysis suggested that amino acids 134–161 form the 'effector' domain that is required for the inhibition of nuclear export of poly(A)-containing cellular mRNAs (Qian et al. 1994), the entire carboxy-terminal half of the protein (amino acids 74–237) might be necessary.

NS1 induces apoptosis in infected cells (Schultz-Cherry et al. 2001), a phenotype that relies on the RNA-binding/multimerization, but not the effector, domain. However, mutations in the RNA-binding/multimerization domain are not sufficient to inhibit the induction of apoptosis, indicating that other viral proteins such as NA (Morris et al. 1999; Schultz-Cherry and Hinshaw 1996) also contribute to the induction of apoptosis.

NS2(NEP)

Encoded by a spliced mRNA (Inglis et al. 1979; Lamb and Choppin 1979), the NS2(NEP) protein comprises 121 amino acids (Lamb and Lai 1980), is phosphorylated, localizes to both the nucleus and cytoplasm of infected cells, and is incorporated into virions (Richardson and Akkina 1991). NS2(NEP) contains a classical nuclear export signal (NES) in its amino-terminal region (O'Neill et al. 1998) and interacts with the cellular nuclear export factor CRM1 (Neumann et al. 2000), which mediates export of proteins containing classical NESs. In cells infected with viruslike particles lacking NS2(NEP), viral RNP complexes are retained in the nucleus. Likely, NS2(NEP) functions by connecting the cellular export machinery with vRNPs through M1 (Akarsu et al. 2003; Yasuda et al. 1993). Based on its role as the viral nuclear export protein, NS2 is now also referred to as NEP.

The NS2 proteins of type A viruses are more conserved than the NS1 protein (76.9 percent vs 64.3 percent); however, neither product is conserved to the extent of other internal proteins (Buonagurio et al. 1986; Kawaoka et al. 1998; Ludwig et al. 1991; Nakajima et al. 1990a, b; Suarez and Perdue 1998).

HEF

The HEF protein of influenza C virus, which is synthesized as a single polypeptide with subsequent trimer formation and then cleaved into two disulfide-linked subunits, HEF1 and HEF2 (Formanowski and Meier-Ewert 1988; Herrler et al. 1979; Herrler and Klenk 1991; Hewat et al. 1984), exists on the virion surface as projections and has a reticular structure consisting mainly of hexagons (Flewett and Apostolov 1967) (see Figure 5). Its structure has been determined by X-ray crystallography (Rosenthal et al. 1998; Zhang et al. 1999). The HEF is composed of an extended, membrane proximal stalklike domain (composed of both HEF1 and HEF2 amino acids) and a membrane distal globular head that consists of HEF1 residues. The head region contains the receptor binding site which is situated on top of the protein. Two regions of significant sequence difference in HEF1, when compared to HA1 (residues 41–73 and 311–366), form the esterase domain which is located under the receptor-binding site. This confirms earlier findings that suggested separate esterase and receptor-binding sites, as di-isopropyl fluorophosphate inhibits only the esterase activity (Muchmore and Varki 1987). Calcium ion is essential for maintenance of the HEF structure. The HEF facilitates binding of influenza C virus to its cell surface receptor, an oligosaccharide containing a terminal 9-*O*-acetyl-*N*-acetylneuraminic acid (Herrler et al. 1985; Rogers et al. 1986).

The receptor-destroying enzyme (esterase) contains the 'catalytic triad' of a serine (position 57), a histidine (position 355), and an aspartic acid residue (position 352) (Rosenthal et al. 1998) that are characteristic for the active sites of esterases. The 9-*O*-acetyl group is critical for the binding of HEF, which does not recognize *N*-acetyl or *N*-glycolyl sialic acid (Rogers et al. 1986; Suzuki et al. 1992). Unlike the NA of type A and B viruses, HEF does not catalyze the cleavage of the α-ketosidic linkage between terminal sialic acid and an adjacent sugar residue, but instead catalyzes the cleavage of the 9-*O*-acetyl group of 9-*O*-acetyl-*N*-acetylneuraminic acid (Herrler et al. 1985; Vlasak et al. 1987). The protein also possesses fusion activity, which requires a low pH optimum (between 5.0 and 5.7) (Herrler et al. 1988; Ohuchi et al. 1982). The acetylesterase activity may be required for entry of the C virus into target cells (Strobl and Vlasak 1993), but not for hemolysis (Herrler et al. 1992). The host cell-dependent variant selection also occurs in influenza C viruses with mutations in the HEF protein (Umetsu et al. 1992). HEF is also acylated, but with stearic acid instead of palmitic acid, as in type A and B HAs (Veit et al. 1990).

Reverse genetics

A major research advance occurred when Palese and colleagues established a system which allows one to generate influenza viruses containing genes derived from cloned cDNA (Enami et al. 1990; Luytjes et al. 1989). While this system allowed, for the first time, modification of the influenza viral genome, it was limited by its low efficiency and the requirement for selection systems (reviewed in Neumann and Kawaoka (1999, 2001, 2002) and Neumann et al. (2002)). In 1999, a system was established for the de novo generation of influenza A virus from plasmids (Neumann et al. 1999) (Figure 18). This system relies on the cellular enzyme RNA polymerase I for intracellular synthesis of influenza viral RNA. Artificial virus generation therefore requires fusion of cDNAs encoding all eight influenza viral genes to RNA polymerase I promoter and terminator sequences, and transfection of these transcription units into eukaryotic cells. Viral RNA synthesized by cellular RNA polymerase I is then replicated and transcribed by the viral polymerase and NP proteins that are provided from RNA polymerase II-driven protein expression plasmids. Although this approach requires cotransfection of cells with 12 different plasmids, it routinely yields 10^8 infectious viruses per ml of supernatant derived from transfected cells. Modifications include the use of ribozymes for the generation of vRNA 3′ ends (Fodor et al. 1999), or – through the combination of RNA polymerase I and II promoters on one plasmid – the synthesis of vRNA and mRNA from one template, thereby reducing the number of plasmids required for rescue to eight (Hoffmann et al. 2000). These approaches also allow the artificial generation of influenza B virus (Hoffmann et al. 2002; Jackson et al. 2002) and Thogotovirus

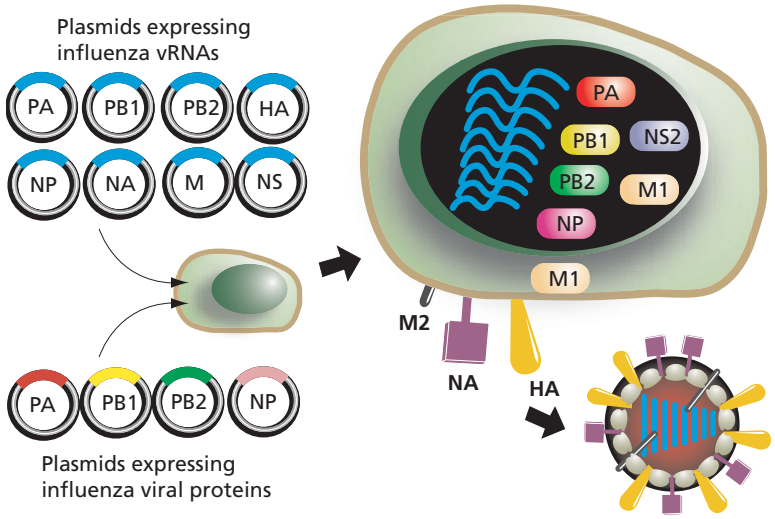

Figure 18 *Reverse genetics procedure. Influenza viral cDNAs are cloned in negative-sense orientation between RNA polymerase I promoter and terminator sequences. In plasmid-transfected cells, all eight influenza vRNAs are transcribed by the cellular enzyme RNA polymerase I. The three polymerase proteins and NP are provided from RNA polymerase II-driven protein expression plasmids. (Courtesy of Yuko Kawaoka.)*

(another member of the *Orthomyxoviridae* family) (Wagner et al. 2001).

The ability to modify the viral genome in any way desired has promoted research in the field tremendously. Current advances attributable to reverse genetics include the identification of factors determining viral pathogenicity (Hatta et al. 2001; Seo et al. 2002), the ongoing reconstruction of the 1918 pandemic virus (Basler et al. 2001; Reid et al. 1999, 2000, 2002; Tumpey et al. 2004), the re-assignment of functions encoded by the influenza B virus BM2 and NB proteins (Hatta and Kawaoka 2003; Hatta et al. 2004; Jackson et al. 2004), and the characterization of influenza viral proteins (Barman et al. 2003, 2004; Bourmakina and Garcia-Sastre 2003; Cross et al. 2001; Elleman and Barclay 2004; Hatta et al. 2001, 2002; Hui et al. 2003; Liu and Ye 2002; Neumann et al. 2000; Wagner et al. 2000; Yao et al. 2001). Moreover, reverse genetics is expected to have an enormous impact on public health by allowing the design and/or characterization of conventional (inactivated) or live attenuated vaccine viruses (de Wit et al. 2004; Hoffmann et al. 2002; Jin et al. 2003, 2004; M. Liu et al. 2003; Ozaki et al. 2004; Schickli et al. 2001; Subbarao et al. 2003; Watanabe et al. 2002; Webby et al. 2004), replication-incompetent virus-like particles (Neumann et al. 2000; Watanabe et al. 2002), or by exploring the potential of influenza virus as a vaccine vector (Shinya et al. 2004; Watanabe et al. 2003).

CLINICAL MANIFESTATIONS AND PATHOGENESIS

The spectrum of symptoms occurring during influenza virus infections is highly variable, ranging from mild respiratory disease with rhinitis or pharyngitis to primary viral pneumonia with a fatal outcome. Rates of asymptomatic infection may be nearly as high as those for symptomatic infection during some epidemics (Foy et al. 1976; Hayslett et al. 1962; Noble 1982). Often a physician's diagnosis is based on the patient's symptoms and the knowledge that influenza activity is occurring in the community. The presence of fever and cough along with sudden onset help distinguish influenza from other respiratory infections caused by other co-circulating respiratory pathogens; however, the physical signs and symptoms of influenza are not distinct enough from those of other respiratory infections to make a definitive clinical diagnosis without laboratory confirmation. In addition, symptoms in certain populations, notably babies, young children, and elderly people, may be atypical. However, during times when influenza is known to be circulating in a community, physicians participating in various studies have been able to diagnose influenza among adults with fever and cough with reported sensitivities and specificities of between 63 and 78 percent and 55 and 71 percent, respectively, compared with viral culture (Boivin et al. 2000; Monto et al. 2000).

Adults

Early symptoms in adults typically include fever, chills, headache, sore throat, dry cough, myalgias, anorexia, and malaise. A fever of 38–40°C that peaks within 24 h of onset is common, but peaks as high as 41°C can also occur. Pyrexia typically lasts 3 days but may last from 1 to 5 days or longer. Other symptoms that occur less frequently include substernal soreness, photophobia and other ocular symptoms, nausea, abdominal pain, and diarrhea (Douglas 1975; Nicholson 1992). Although most

symptoms typically resolve within a week, cough and malaise may persist for 1 or more weeks after fever has subsided. Type A influenza viruses of the H1N1, H2N2, and H3N2 subtypes as well as type B influenza viruses cause a similar spectrum of illness (Frank et al. 1985; Nicholson 1992; Spelman and McHardy 1985). However, in general, the frequency of severe infections requiring hospital admission or causing death is lower for influenza B than for influenza A(H3N2) viruses (Thompson et al. 2003, 2004). Elderly, debilitated people may have signs and symptoms that are not immediately recognized as influenza. Symptoms in uncomplicated disease in this group include lassitude, anorexia, cough, rhinitis, unexplained fever, general malaise, and confusion.

Infants and children

Influenza A and B viruses are significant causes of both upper and lower respiratory tract illness in children (Glezen 1980; Glezen et al. 1980a; Kim et al. 1979). In children, symptoms are similar to those in adults, but gastrointestinal symptoms such as vomiting, abdominal pain, and diarrhea are seen more frequently. Maximum temperatures also tend to be higher in children than in adults, and febrile convulsions can occur. In addition, myositis, croup, and otitis media occur more frequently in children. Influenza infection of neonates can be life-threatening and may be manifest only as an unexplained febrile illness (Meibalane et al. 1977). Hospitalization rates for infants and young children may increase during influenza outbreaks (Glezen et al. 1980b; Kim et al. 1979).

Complications

Complications of the upper respiratory tract after influenza infection include bacterial sinusitis and otitis media. Lower respiratory tract complications include exacerbation of chronic obstructive pulmonary disease and chronic congestive heart failure, croup, bronchitis, bronchiolitis, wheezing attacks in asthmatics, and pneumonia (primary viral pneumonia, secondary bacterial pneumonia or combined bacterial and viral pneumonia) (Betts 1995; Nicholson 1992).

Primary influenza pneumonia, which often develops abruptly and progresses rapidly, was described in detail during the 1957/8 Asian influenza pandemic (Hers et al. 1957; Louria et al. 1959). This type of pneumonia is uncommon, and occurs mainly among those at increased risk for complications of influenza. Rapid respiration rate, tachycardia, cyanosis, high fever, and hypotension are frequent symptoms. Diffuse pulmonary infiltrates and acute respiratory failure with a high mortality rate are also features of this disease. Combined viral and bacterial pneumonia is more common than primary viral pneumonia and may be clinically indistinguishable from it.

Secondary bacterial infections typically occur 5–10 days after initial onset of influenza symptoms and are responsible for most pneumonias during influenza epidemics. Productive cough, pleuritic chest pain, and chills are common symptoms of this type of pneumonia. *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Hemophilus influenzae* are the organisms most commonly involved (Schwarzmann et al. 1971). These illnesses respond to appropriate antimicrobial agents and have a lower case fatality rate than primary viral pneumonia.

Other reported but less frequent complications of influenza include myositis, myocarditis and pericarditis, acute renal failure, encephalopathy, encephalitis, transverse myelitis, Guillain–Barré syndrome and a range of other neurological complications, Reye's syndrome, and toxic shock syndrome (Betts 1995; Noble 1982).

Higher rates of spontaneous abortion, stillbirths, and premature births were reported among pregnant women during the major pandemics of 1918/19 and 1957/8 (Bland 1919; Hardy et al. 1961; Woolston and Conley 1918); increased maternal risk for death following influenza infection was also documented (Eickhoff et al. 1961; Greenberg et al. 1958). In addition, case reports (Irving et al. 2000; Schoenbaum and Weinstein 1979; Shahab and Glezen 1994) and a retrospective study during 17 interpandemic influenza seasons demonstrated an increased risk for influenza-related hospitalization for women in their second or third trimesters of pregnancy (CDC 2004).

Serious complications of influenza most often occur in people 65 years of age and older, in the very young, and in those of any age with underlying chronic cardiac, pulmonary, or metabolic disease (Barker and Mullooly 1980). Complications in elderly people, particularly among those with pulmonary, cardiovascular, or other chronic diseases, account for most of the mortality in influenza epidemics (Eickhoff et al. 1961). The highest rates of hospitalization and death following influenza infection occur in those at opposite ends of the age spectrum, i.e. less than two or 65 years and older. Recent studies have shown that otherwise healthy children aged 6–23 months of age are at a substantially increased risk for influenza-related hospitalization, compared to older healthy children and healthy adults (Izurieta et al. 2000; Neuzil et al. 2000). In general, hospital admissions are 10–20 times higher than the mortality rate in the elderly (Barker and Mullooly 1980; Glezen et al. 1987), but are an order of magnitude higher for children under 5 years of age (Thompson et al. 2004).

Pathogenesis

Much remains to be learned about the pathogenesis of influenza virus replication and its relationship to the clinical manifestations and complications of the infection.

Many studies to investigate the pathogenesis of influenza infections were conducted during the 1957/8 pandemic of Asian influenza (Hers and Mulder 1961; Walsh et al. 1961). These studies demonstrated that the principal site of replication is the columnar epithelial cells, but histological studies indicate that viral replication can occur throughout the respiratory tract. Infected ciliated columnar cells become vacuolated and lose their cilia, and infected mucosal and ciliated epithelial cells become necrotic and desquamate. In studies in which bronchoscopy was conducted on, or nasal and bronchial biopsy specimens were taken from, individuals with uncomplicated acute influenza infections, inflammation of the larynx, trachea, and bronchi, and desquamation of ciliated columnar epithelium into the lumen of the bronchus were observed. Regeneration of the respiratory epithelial cells takes ca. 3–4 weeks, during which time pulmonary function abnormalities may persist (Hall et al. 1976). In these typical cases of influenza in which infection is confined to the respiratory tract, prostration, fever, and myalgia often seem to be disproportionate to objective clinical signs or observed pathological changes.

Lungs from fatal cases of primary viral pneumonia most notably show hyaline membrane coverage of alveolar walls together with extensive intra-alveolar edema and hemorrhage. Tracheitis and bronchitis are also observed (Hers and Mulder 1961; Martin et al. 1959). Patients with secondary bacterial pneumonia have changes characteristic of bacterial pneumonia in addition to the tracheobronchial findings of influenza.

The occurrence of systemic illness and fever suggests dissemination of virus via the blood stream, but systematic studies (Kilbourne 1959; Minuse et al. 1962) and limited case reports (Lehmann and Gust 1971; Naficy 1963) suggest that viremia is detected only rarely.

Apoptosis

Influenza A and B viruses induce apoptosis in both permissive (MDCK) and non-permissive cells (Takizawa et al. 1993; Hinshaw et al. 1994), which can be blocked by the *bcl*-2 product (Hinshaw et al. 1994). Apoptosis induced by influenza virus infection seems to involve activation of the Fas antigen-encoding gene (Takizawa et al. 1995) as well as the PKR, and IFN type I secretion. The latter sensitizes cells to apoptosis signaling through FADD/caspase-8 activation (Balachandran et al. 2000). The role of apoptosis in the clinical signs and symptoms of influenza is controversial. Indirect evidence indicates that programmed cell death could help reduce viral load and pathology (inflammation and tissue damage), yet others have found that activation of caspase 3, a critical enzyme involved in apoptosis, enhances influenza replication (Wurzer et al. 2003). The PB1-F2 protein induces apoptosis in various cell types, including human monocytic cells, leading to the hypothesis that this protein functions to kill host immune cells responding to influenza virus infection (Chen et al. 2001). Influenza virus-infected cells undergoing apoptosis are readily engulfed by macrophages (Shiratsuchi et al. 2000). Infection of macrophages but not dendritic cells can trigger apoptosis (Bender 1998). It has also been reported that specific types of differentiated airway cells may undergo necrotic cell death, promoting inflammatory damage in the airway (Brydon et al. 2003).

MX PROTEIN

The pathogenesis of influenza virus infection is modulated by parameters specified by both the virus and the host. Although the available evidence suggests that numerous host genes have antiviral functions, most of them have not been identified and characterized. One exception is the Mx family of proteins, which mediate inhibition of orthomyxovirus replication (Staeheli 1990). This family of proteins is induced directly by viral infection as well as by type I interferons and may act either in the cytoplasm, as in the case of the human MxA protein, or in the nucleus, as in the case of the mouse Mx1 protein (Pavlovic et al. 1992; Noah et al. 2003). The Mx proteins belong to the dynamin superfamily of large GTPases (reviewed in Haller and Kochs 2002). The Mx GTPases seem to constitute an intracellular surveillance system that monitors the cell for viral infection by sensing viral nucleocapsids or viral ribonucleoprotein complexes. These viral components are thought to be derailed in their intracellular traffic and rendered inactive by sequestration. Specifically, MxA inhibits viral protein synthesis and genome amplification, suggesting that MxA protein interfered with either transcription, intracytoplasmic transport of viral mRNAs, viral protein synthesis, or translocation of newly synthesized viral proteins to the cell nucleus (Horisberger 1992; Turan et al. 2004; reviewed in Haller and Kochs 2002).

Immune response

INNATE IMMUNITY

During primary infection with influenza, the early host protective response involves the immediate action of cells such as phagocytes, natural killer (NK) cells, and B cells, as well as soluble factors including complement, IFN, cytokines, and chemokines. Cells and soluble factors converge to reduce the permissiveness of cells and tissues for the replication and spread of the invading virus (Kase et al. 1999; Kaufmann et al. 2001; Medzhitov and Janeway 2000; Siren et al. 2004). This early host response is triggered by receptors which recognize non-specific alarm signals of viral infection (Coccia et al. 2004; Ehrhardt et al. 2004; Lund et al. 2004; Yoneyama et al. 2004). These receptor molecules are expressed in the germline of the host. In contrast, the receptors and effectors of the adaptive immune system (antibodies and

T cell receptors) result from gene rearrangements and are pathogen-specific, leading to the establishment of immunological memory. Germline immune receptors such as the Toll-like receptors (TLR) are expressed in a variety of cells such as macrophages, dendritic cells, and intestinal epithelium. TLR-3 and TLR-7 are involved in the recognition of viral dsRNA and ssRNA respectively, promoting dendritic cell maturation and activation of IFN production (Lund et al. 2004). Viral dsRNA is also involved in the activation of proteins with antiviral activity such as the kinase PKR, which inhibits protein translation and may trigger apoptosis (Katze et al. 1988). The cellular response to infection has been studied using DNA microarray techniques that allow the analysis of the gene expression changes in cultured infected cells (Geiss et al. 2001, 2002). Using this approach, it was noted that influenza infection causes profound changes in the expression of a large number of cellular genes involved in interferon production and signaling, apoptosis, and oxidative stress. Influenza-infected patients trigger the activation of antiviral genes and production of cytokines, such as interleukin (IL)-6 and IFN-alpha which reach their highest concentration in nasal fluids within 48 h of infection, correlating with the onset of fever (Hayden et al. 1998). Other cytokines, such as TNF-alpha and IL-8 reach maximum levels 4–5 days after infection. IL-8 is temporally correlated with lower respiratory tract involvement. Influenza viruses have evolved mechanisms to counter the innate antiviral responses of the host. The viral NS1 protein antagonizes interferon production and the activation of PKR in influenza-infected cells (Garcia-Sastre et al. 1998; Lu et al. 1995; Wang et al. 2000).

Besides its importance in the early arrest of viral replication, the innate immune responses to influenza interface with and condition the acquired cellular immune response. IFN and certain cytokines induced by viral infection, such as IL-12, have a powerful influence on the nature of the adaptive immune response (Janeway and Medzhitov 2002). Evidence from a murine model of influenza shows that type I IFN plays a critical role coordinating the immune response to viral infection, by reducing inflammation (Durbin et al. 2000). The enhanced pathology that was observed in mice that lacked IFN production was not attributable to the absence of the antiviral activity of IFN but to the excess of pro-inflammatory mediators.

A new type of innate antiviral mechanism, termed RNA interference (RNAi), may also play a role in controlling influenza replication during the early stages of infection. This system involves the formation of a ribonucleoprotein complex that targets viral RNA for degradation in a sequence specific manner. Experimental studies in tissue culture and in laboratory animals showed that RNAi can cause a marked reduction of influenza virus replication. The influenza virus NS1 protein was found to antagonize RNAi activity, suggesting that this innate immune mechanism may be functional in vivo. It is not known if this antiviral mechanism is functional in human influenza infection (Ge et al. 2003, 2004; W.X. Li et al. 2004; Tompkins et al. 2004).

ADAPTIVE IMMUNITY

Antigen-nonspecific innate immune mechanisms generally inhibit, but do not eliminate, viral infection. They restrict viral replication until the more effective adaptive response is fully engaged. The adaptive immune response to infection with influenza viruses leads to induction of both virus-specific B- and T-cell immune responses to clear infection and generate long-lasting specific immunologic memory. Antibodies are made against the viral external glycoproteins HA and NA as well as the internal type-specific proteins NP and M1 (see section on Antigens). Neutralizing antibody directed against the HA is the primary immune mediator of protection from infection and clinical illness due to influenza viruses. Both mucosal and systemic immunity contribute to resistance to infection and disease (Clements et al. 1983, 1986). Influenza-specific lymphocytes have been detected in blood and lower respiratory tract secretions of infected subjects (Jurgensen et al. 1973; Yewdell and Hackett 1989). The primary cytotoxic T-cell response is detectable in blood after 1–2 weeks but is relatively short lived (Ennis et al. 1981). Evidence from animal models indicates that cytotoxic T-cell responses at mucosal surfaces play an important role in host protection (B. Liu et al. 2003a).

HUMORAL IMMUNE RESPONSE

Antibody to HA mediates neutralization of virus, complement fixation, prevention of virus attachment, and antibody-dependent cellular cytotoxicity. Resistance to infection is correlated with serum anti-HA antibody levels (Dowdle et al. 1973; Hobson et al. 1972) and can be demonstrated by protection against challenge after passive transfer of immune serum in a mouse model (Virelizier 1975). More recent studies have shown that protection from live virus challenge is associated with local neutralizing antibody and secretory IgA as well as serum anti-HA antibody (Clements et al. 1986; Johnson et al. 1986). Although antibodies to NA are inefficient in neutralizing influenza viruses, they restrict virus release from infected cells, reduce the intensity of infection and enhance recovery (see section on Antigens).

Serum antibody to HA can persist for decades and retrospective serosurveys suggest that a limited number of influenza subtypes have recycled (Masurel and Marine 1973). Decade-long persistence of immunity was demonstrated dramatically when influenza A (H1N1) strains, similar to viruses that had circulated in 1950, spread throughout the world during 1977/8. Little disease occurred in individuals born before 1950, indi-

cating that substantial immunity remained after almost 30 years. Disease occurred in people <20 years old, however, irrespective of whether they were infected by influenza viruses of the H3N2 subtype. This and numerous observations during the pandemics of 1957 and 1968 suggest that intersubtypic immunity is weak in humans. In contrast, intrasubtypic immunity to influenza A (H3N2) viruses in adults can last for 4–7 years and include two or more variants of the same subtype, depending on the extent of antigenic drift (Couch and Kasel 1983).

The fact that a repeat infection with an antigenically related strain boosts the antibody response to the first virus encountered was originally described in 1953 by Davenport and colleagues (1953). This phenomenon, known as 'original antigenic sin,' is believed to be a selective anamnestic response orientated toward both the HA and the NA antigens experienced during the original infection. Thus, cross-reactive epitopes will stimulate a predominant secondary antibody response whereas new epitopes in the reinfecting variant induce a primary response. The precise importance of this phenomenon to immunity induced by infection or vaccination is unknown, but observations on original antigenic sin suggest that induced immunity during sequential infections may be biased toward older, less relevant strains rather than the current infecting strain.

Sequence analysis of the HA genes of monoclonal antibody escape variants, along with field isolates and location of amino acid changes on the three-dimensional structure of the HA, have defined five antibody-combining sites. The relationship of these sites to antibodies produced via natural infection has yet to be determined precisely, but the specificity of the antibody response to HA seems to be limited in humans and may vary from individual to individual (Natali et al. 1981; Wang et al. 1986). A limited range of specificities of anti-HA antibodies in individual mice and rabbits have also been demonstrated (Lambkin et al. 1994; Lambkin and Dimmock 1995). These findings may have implications for antigenic drift and the epidemiological success of influenza viruses in humans.

Among children with no previous exposure to influenza viruses, vaccination with live-attenuated influenza viruses results in the appearance of serum anti-HA IgM, IgG, and IgA antibodies within 2 weeks. IgM and IgA antibodies decline after this time, but the IgG response peaks after ca. 6 weeks, declines over the next 6 months or so, and then remains relatively stable for 2–3 years (Murphy and Webster 1996; Murphy et al. 1982). Antiviral IgA, IgG, and IgM responses can be detected in nasal secretions in most individuals and persist for several months (Murphy and Clements 1989; Wright et al. 1983). A secondary response to infection in primed young adults results in serum IgG and IgA and mucosal IgA in most cases. Serum hemagglutination inhibition (HAI) responses decline initially after infection, but may then remain quite stable for years (Ada and Jones 1986). Serum antibodies to NA are rarely induced in primary infection and generally occur after re-exposure to NA of the same subtype. Antibodies to type-specific NP and M1 proteins are boosted via reinfection and may help diagnose a recent exposure to virus.

T-CELL RESPONSES

Antibodies and T cells play complementary roles in clearing the infection and promoting recovery. $CD4^+$ (Th1 and Th2) and $CD8^+$ T-cell responses to influenza are type-specific and are largely cross-reactive among influenza A viruses of different subtypes. T-cell recognition of antigen is restricted by the major histocompatibility complex (MHC) molecules, and the ability to respond to a given viral epitope depends on the HLA phenotype of an individual, a fact that complicates various T-cell vaccine approaches to vaccination against influenza. In naturally infected humans the $CD4^+$ cell response recognizes epitopes on the internal proteins NP and M1 as well as the surface proteins NA and HA.

$CD4^+$ T cells provide help for the activation of $CD8^+$ T cells by virtue of their ability to activate antigen presenting cells (dendritic cells, macrophages, etc.) primarily via CD40–CD40L interactions. Activated antigen presenting cells are essential for CD28 signaling to $CD8^+$ T cells leading to vigorous protective cytotoxic cell response to influenza infection (Prilliman et al. 2002; Schoenberger et al. 1998). The $CD4^+$ T cells are indispensable for an effective B cell antibody response to influenza. $CD4^+$ T cells can also enhance the proliferation of virus-specific $CD8^+$ T cells and maintaining $CD8^+$ T-cell memory capacity (Doherty et al. 1997).

The $CD8^+$ cytotoxic T lymphocyte response is directed to multiple surface and internal influenza proteins, in which many epitopes are potentially recognized, as determined by their binding to class I MHC molecules (Gianfrani et al. 2000; Gotch et al. 1987; Jameson et al. 1998; Robbins et al. 1997; Yewdell and Hackett 1989). However, a limited subset of immunodominant epitopes is recognized by lymphocytes primed by influenza infection (Belz et al. 2000; Yewdell and Bennink 1999).

Cytolytic $CD8^+$ effector cells fall into two subpopulations based on cytokine secretion. Both subpopulations lyse targets by production of perforin or Fas. Type 1 $CD8^+$ T cells (Tc1) secrete IFN-γ, whereas type 2 $CD8^+$ T cells (Tc2) secrete IL-4 and IL-5. Influenza virus infections elicit both Tc1 and Tc2 cells specific for class I-restricted epitopes. Tc1 cells are thought to contribute to the protective antiviral response, whereas the Tc2 component may act to limit the lung-associated pathology associated with influenza virus infection. Recent animal model studies have shown that both $CD4^+$ and $CD8^+$ T cells can contribute to immunity to influenza viruses. Animals that are deficient in both

$CD4^+$ and $CD8^+$ T cells do not survive influenza infection, but animals deficient in only $CD4^+$ or $CD8^+$ T cells are able to clear virus (Eichelberger et al. 1991a, b; Flynn et al. 1998; Lightman et al. 1987). The increased severity of influenza infections in geriatric patients has been correlated with a combination of functional impairments in their T-cell responses to influenza (Deng et al. 2004; Katz et al. 2004; Po et al. 2002).

The emergence of viral variants with altered surface antigens is a hallmark of influenza biology. Selection of antigenic variants is not limited to mutations in the HA and NA which allow escape from antibody neutralization. Evidence from influenza infections in humans and experimental animals shows that T-cell responses can select escape viruses with amino acid changes in the T-cell epitopes of the viral proteins (Boon et al. 2002; Price et al. 2000).

ANTIGENS

Polymerase proteins

There is no detectable antibody response to the polymerase proteins in convalescent sera. Their extremely low abundance in infected cells may contribute to this observation. These proteins have not been examined extensively for antigenic variants, although monoclonal antibodies to PA and PB2 are now available (Barcena et al. 1994). Cytotoxic T lymphocytes can recognize each of the three polymerase proteins (Bastin et al. 1987b; Bennink et al. 1984, 1987; Reay et al. 1989). Some viral strains produce an additional polypeptide, termed PB1-F2, encoded by the *PB1* gene segment (W. Chen et al. 2001). The PB1-F2 protein is translated from a downstream AUG initiation codon in an alternative reading frame. PB1-F2 is a mitochondria-targeted pro-apoptotic protein that has been associated with some emerging pandemic strains. This polypeptide induces CD8 T-cell responses in mice.

HA

The HA antigen is the major inducer of protective immunity to influenza viruses. Influenza A virus HAs show subtype specificity and are thought to possess five antigenic sites in the three-dimensional structure (Wiley et al. 1981; Wiley and Skehel 1987), although some subdivision and overlap of these areas have been noted (Caton et al. 1982; Daniels et al. 1983). For H3 virus strains (Wiley et al. 1981; Wiley and Skehel 1987), the sites are A, B, C, D, and E, and for the H1 strains they are Ca1, Ca2, Cb, Sa, and Sb (Caton et al. 1982). Each of these sites was derived from amino acid sequence changes in antigenic variants selected with monoclonal antibodies, as well as in natural variants. Monoclonal antibodies to each of the five sites neutralize the infectivity of the virus (Wiley and Skehel 1987). Mutations that result in gain or loss of N-linked glycosylation sites in the HA can result in major changes in the antigenic structure of the virus (Skehel et al. 1984).

Helper T lymphocytes recognize several distinct regions of the HA1 and HA2 subunits located either on the surface or the interior of the intact molecule, as well as conformational determinants on the HA (Yewdell and Hackett 1989). Helper T lymphocyte recognition includes specificity for determinants on the variable regions of the molecule to which antibodies are also directed (Hackett et al. 1983; Mills et al. 1988). The immunodominant peptide most readily recognized by both subtype-specific and cross-reactive helper T lymphocyte clones is HA1 306–328 (H3 numbering system). Most memory T-cell clones recognize sites B, C, and E (HA1 56–76; H3 numbering) (Barnett et al. 1989; Graham et al. 1989). Residues important in antibody recognition affect T-cell recognition (Barnett et al. 1989; Graham et al. 1989), indicating that both B and T cells may recognize similar sites on the HA and hence that both systems may provide selective immune pressure. Cytotoxic T cells recognize both the HA1 and HA2 subunits (Wabuke-Bunoti and Fan 1983; Wabuke-Bunoti et al. 1984).

NP

Although a type-specific protein, the NP of influenza A viruses shows antigenic variation (Herlocher et al. 1992). It contains at least three non-overlapping antibody-binding areas (Van Wyke et al. 1980), one of which is highly conserved. Monoclonal antibody binding to this site inhibits transcription of viral RNA in vitro (Van Wyke et al. 1981). The NP epitopes recognized by dominant helper T lymphocytes in humans are located in residues 206–229, whereas those of mice are found in residues 260–283, with the distinct specificity of these regions depending on haplotypes. As a major antigen recognized by cytotoxic T lymphocytes, the NP possesses several T cell-specific epitopes that are conserved among human influenza A viruses (Bastin et al. 1987a; Bodmer et al. 1988; Yewdell and Hackett 1989). Transfer of cytotoxic T lymphocytes specific to NP protects mice from lethal influenza challenge (Taylor and Askonas 1986). The protective role of HLA-restricted cytotoxic T lymphocytes that recognize NP epitopes is evidenced by the identification of virus variants with altered NP epitopes which emerged in sequential chronological order with the cognate CTL; indicative of escape from CTL immunity (Boon et al. 2002).

NA

The subtype-specific influenza A virus NA has four antigenic sites, each consisting of multiple epitopes

(Webster et al. 1984). These antigenic sites differ in that antibodies to some, but not other, sites inhibit enzyme activity. Amino acids that change during antigenic drift cluster mainly in the distal surface loops connecting the various strands of β-sheets (Air et al. 1985).

Antigenic structures of the N9 NA have been extensively studied. Analysis of the crystal structure of a complex of N9 NA from A/tern/Australia/G75 with the Fab fragment of monoclonal antibody NC41 (Colman et al. 1987; Tulip et al. 1992) shows that the antibody contacts the NA over a surface area of 900 $Å^2$, comprising 19 amino acid residues localized on five polypeptide loops surrounding the enzyme active site. Site-specific mutagenesis indicates that, of the 19 amino acids in this epitope, only a few provide the critical contacts required for antibody recognition (Nuss et al. 1993). These findings support the observation of limited sites of sequence changes and local changes to the structure in escape mutants (Tulip et al. 1991; Varghese et al. 1988; Webster et al. 1987), implying (1) that antibody escape mutants are selected only when they contain changes at critical sites, or changes that introduce bulky side-chains capable of sterically preventing antibody attachment, and (2) that the other contact residues are providing 'passive surface complementarity' (Nuss et al. 1993). Antibodies to NA are inefficient in neutralizing the virus, but reduce plaque sizes in cell culture (Jahiel and Kilbourne 1966; Kilbourne et al. 1968; Rott et al. 1974). In agreement with these findings, immunity to NA in natural infection has only a small role in influenza protection as exemplified by the 1968 pandemic, whose causative agent possessed the NA from a previously circulating human virus; the immunity to the NA that existed in the human population did not protect humans from pandemic influenza (Cockburn et al. 1969). However, in experimental infections in animal models, passive transfer of monoclonal antibodies to NA or immunization with the vaccinia virus expressing the NA protected animals against lethal challenge (Webster et al. 1988) or reduced virus titers (Rott et al. 1974; Schulman et al. 1968). Helper and cytotoxic T lymphocyte responses to NA were found in influenza virus-infected mice, but were limited compared with responses to the HA, NP, and M1 (Caton and Gerhard 1992; Hurwitz et al. 1985; Reay et al. 1989; Wysocka and Hackett 1990).

M1

Even though this protein is considered a highly conserved type-specific antigen, some variations have been found among influenza A strains studied with a panel of monoclonal antibodies (Herlocher et al. 1992; Van Wyke et al. 1984). Helper T lymphocytes specific for the M1 protein are cross-reactive between viruses of different subtypes (Hurwitz et al. 1985). M1 is also recognized by cytotoxic T lymphocytes (Gotch et al. 1987). A CTL epitope in the M1 protein that is recognized by human CD8 T cells was shown to mediate protection in transgenic mice expressing the cognate human HLA molecule (Plotnicky et al. 2003).

M2

Antibodies to the M2 protein have been found in humans infected with influenza A virus (Black et al. 1993). Passively transferred monoclonal antibodies reduced virus replication in mice (Treanor et al. 1990), and it has recently been shown that M2 protein plays a role in recovery from infection in mice (Slepushkin et al. 1995). Some antigenic variation can be found among the M2s as a result of amino acid changes in the ectodomain (Zebedee and Lamb 1988). However, antibodies elicited by M2 have been shown to mediate protection against different virus subtypes in animal models (Neirynck et al. 1999). Cytotoxic T lymphocytes specific for M2 have been isolated from convalescent mice and humans (Gianfrani et al. 2000; Jameson et al. 1998).

NS1

The influenza A virus NS1 proteins from different animal species cross-react with polyclonal antibodies. Although a panel of monoclonal antibodies distinguishes avian virus NS1 from those of human, swine, and equine strains, there is no evidence of antigenic variations among the latter group of proteins (Brown et al. 1983). Cytotoxic T lymphocytes recognizing NS1 are highly cross-reactive (Bennink and Yewdell 1988).

NS2

The antigenic properties of NS2 are poorly understood; however, mouse cytotoxic T lymphocytes specific for this protein have been found (Yewdell and Hackett 1989).

Host range restriction

Multiple genetic factors affect host range restriction for influenza viruses. Changes in host range can parallel changes in pathogenicity. At present, more is known about how particular amino acid changes at positions in or near the receptor-binding pocket of the hemagglutinin confer different receptor specificities and thus different host ranges. These receptor-binding specificities correspond to the composition of the receptor at the replication site in the host (see section on Receptor binding).

There is also indirect evidence that other genes, particularly the *NP* and *NA* genes, play a role in host range restriction. For example, replacement of the *NP* gene of an avian virus with the *NP* gene of a human virus alters

host range (Scholtissek et al. 1978a), and phylogenetic analyses of *NP* gene sequences have shown that there are five distinct host-specific lineages (Gammelin et al. 1990; Gorman et al. 1990a). Other internal genes of influenza A viruses also apparently play a role in host range and virulence (Klenk and Rott 1988). The PB2 subunit of the polymerase complex plays a role in the restriction of avian influenza viruses for certain mammalian species (Subbarao et al. 1993). Recent studies revealed that amino acid 627 of PB2 modulates the replication efficiency of avian influenza viruses in mice (Hatta et al. 2001).

EPIDEMIOLOGY

Although human type A and B influenza viruses were not isolated until 1933 and 1940, respectively, descriptions of epidemics and pandemics of respiratory disease with characteristics suggestive of influenza have been recorded for over four centuries (see section on Historical record). Certain well documented epidemiological features of modern epidemics of influenza also emerge from the early accounts. Epidemics of varying severity occurred at irregular intervals, caused the highest mortality in elderly people, and were thought to have spread from Asia. These records detail epidemics of cough, fever, chills, and muscle aches that affected many people of different ages within a short time.

An epidemic of influenza is an outbreak of disease in a circumscribed location, which may affect a town, a city, or an entire country. Localized epidemics within a community often have a characteristic pattern in which the epidemic begins abruptly, peaks within 2–3 weeks and has a total duration of 5–8 weeks (Glezen and Couch 1978). The spread of influenza virus through a community typically causes large increases in medical visits for febrile respiratory disease (Glezen 1982). Absence from school due to influenza often occurs early in the epidemic, and school children are believed to be important in disseminating the virus in the community. Although reports of increased numbers of children with febrile respiratory illness are often the first indication that influenza is circulating in a community, it is not uncommon for a laboratory-confirmed outbreak in a nursing home to be the first report that influenza is present. Absence from work, hospitalization for pneumonia, and other complications of influenza, and death due to pneumonia and influenza and its complications all tend to peak later during an epidemic.

The size of outbreaks and epidemics that occur during the interpandemic intervals is quite variable, but are almost always smaller than those that occur following the introduction of a new virus subtype. The size of epidemics and their impact reflect the interplay between the extent of antigenic variation of the virus, the extent of immunity in the population and the population groups that are most affected in a given year.

A pandemic of influenza is an epidemic of disease that involves most if not all age groups on several continents. Influenza experts agree that at least three true pandemics of influenza have occurred during the past century: Spanish influenza in 1918, Asian influenza A(H2N2) in 1957 and Hong Kong influenza A(H3N2) in 1968. Human infections with highly pathogenic avian influenza A(H5N1) viruses have raised the specter of the emergence of another influenza pandemic due to unprecedented human exposure to these viruses causing epizootics in several Asian countries in 2004.

Current epidemiology

The simultaneous circulation of two subtypes of influenza A together with influenza B viruses since 1977 has made the current epidemiology of influenza unusually complex. Influenza B viruses have circulated continuously in humans since their first isolation in 1940, whereas influenza A(H3N2) viruses have been present since their emergence in pandemic form in 1968. Unlike the situation in 1957 and again in 1968 when new pandemic strains totally replaced the previously circulating influenza A strains, the influenza A(H1N1) viruses that emerged in 1977 were unable to supplant viruses of the A(H3N2) subtype. Instead, two distinct subtypes of influenza A viruses have co-circulated worldwide since then (see Figure 1).

Prevalence of these three groups of viruses may vary temporally and geographically within a country (Chapman et al. 1993) and between countries and continents during a given influenza season (World Health Organization 1996). In the USA the circulation of influenza A(H3N2) viruses has, in recent years, been associated most often with excess pneumonia and influenza (P and I) mortality. Major peaks of excess P and I mortality were documented by the US 121 Cities Mortality Reporting System during the 1989/90 and 1993/4 influenza seasons, during which influenza A(H3N2) viruses accounted for over 98 percent of the viruses reported.

Transmission and seasonality

It is generally accepted that influenza viruses are spread primarily by aerosols of virus-laden respiratory secretions that are expelled into the air during coughing, sneezing, or talking by an infected person (Betts 1995; Moser et al. 1979). Spread by direct contact is, however, also possible. The incubation period for influenza is relatively short (1–4 days), and the explosive nature of influenza epidemics and pandemics and simultaneous onset in many people suggest that a single infected person can transmit the virus to a relatively large number of susceptible individuals.

It is also generally accepted that influenza viruses are maintained in humans only by direct person-to-person spread, as there is no firm evidence for reintroduction from latently or persistently infected individuals. This is supported by evidence from local and global surveillance of influenza viruses, which has shown that antigenic variation and the consequent epidemiological behavior of influenza viruses follow a relatively uniform pattern, each successive antigenic variant replacing the previously circulating one in such a way that the co-circulation of distinct antigenic variants of a given subtype occurs for relatively short periods (Stuart-Harris et al. 1985; Cox and Bender 1995; Smith et al. 2004). These data have shown that consecutive epidemics in a community are caused by the reintroduction of antigenically drifted, genetically distinct influenza viruses. Intensive community-wide surveillance in large population centers has shown that influenza activity can often be detected during the summer months (Fox et al. 1982; Monto and Kioumehr 1975). Global influenza surveillance also indicates that influenza viruses are generally isolated every month from humans somewhere in the world (Noble 1982; World Health Organization 1996).

The seasonality of influenza activity has been well documented in many countries with temperate climates in Europe, North America, and Asia. In these countries, influenza epidemics generally occur from December to March. Evidence that survival of influenza viruses in an aerosol is favored by low relative humidity and low temperature (Hemmes et al. 1960; Schaffer et al. 1976) is often cited as an explanation for winter seasonality of influenza in temperate climates. Seasonality in tropical or subtropical climates is less well studied; however, influenza viruses may be isolated throughout the year, with peaks of activity often occurring in the summer months (Reichelderfer et al. 1989). Other reports have suggested that peak influenza activity in tropical and subtropical areas may follow changes in weather such as the onset of the rainy season (Rao et al. 1982). The environmental and epidemiological factors responsible for these observations remain to be elucidated.

Antigenic drift and its impact

The epidemiological success of influenza viruses is largely due to the two types of antigenic variation that occur in the HA and the NA. Antigenic variation renders an individual susceptible to new strains – despite previous experience with other influenza viruses. The first kind of variation, called antigenic drift, occurs with both influenza A and B viruses, and is the gradual alteration of the structure of the protein by single amino acid substitutions (mutation) in the HA and NA within type B influenza viruses or within a given subtype of influenza A viruses. This kind of variation is the result of positive selection of spontaneous mutants by neutralizing antibodies (Bush et al. 1999; Plotkin and Dushoff 2003). The amino acid changes result in the inability of antibody to previous strains to neutralize the mutant virus. Variations in the amino acid sequences of the HA and NA occur at a rate of <1 percent per year during antigenic drift.

Antigenic drift variants are responsible for periodic epidemics that occur between pandemics. Thus, influenza among humans is caused by distinguishable antigenic variant strains of influenza A and B viruses that emerge and become predominant over a period of 2–5 years, only to be replaced by the subsequently successful antigenic variant.

Phylogenetic analyses have revealed that *HA* genes of human influenza A and B viruses have a regular relationship between the isolation date and their position on the evolutionary tree. When evolutionary rates are estimated by regression of the year of isolation against the number of nucleotide or amino acid substitutions from a common ancestor (A/Puerto Rico/8/34, A/USSR/90/77, A/Aichi/2/68, and B/Lee/40 for the old A(H1N1), contemporary A(H1N1), A(H3N2), and B viruses, respectively), it is apparent that the *HA* genes of human influenza A viruses of the H1N1 and H3N2 subtypes evolve at about the same rates, whereas *HA* genes of influenza B viruses evolve more slowly (Table 3). Recent phylogenetic analyses have also shown that, although co-circulating lineages of *HA* genes of influenza B viruses can co-exist longer than for influenza A *HA* genes, the overall patterns and the rates of evolution of the *HA* genes of these two types of influenza viruses are more similar than was previously believed (Cox and Bender 1995).

When amino acid changes in the HAs of field strains of influenza A(H3N2) viruses are plotted on the three-dimensional structure of the HA, it is apparent that much of the surface of the molecule has been altered by amino acid substitutions during the circulation of these viruses since 1968 (Figure 19). At least four changes that can be assigned to at least two antigenic sites have been observed between major epidemic strains of human influenza A viruses (Wilson and Cox 1990). Thus, the HA molecule seems to have a vast potential for antigenic change within a subtype as well as between subtypes without jeopardizing its function. This feature along with the apparent extensive nature of the antigenic regions in the HA molecule (Caton et al. 1982; Wilson and Cox 1990) make it extremely difficult to predict future antigenic variants of influenza before they arise.

MORBIDITY

Quantifying morbidity due to influenza is difficult. The spectrum of symptoms occurring during influenza virus infections is quite variable. In addition, many other respiratory pathogens cause influenza-like illness, so

Table 3 *Evolutionary rates for the HA1 portion of the* HA *gene and protein*

Virus	Period	Number	Nucleotide changes per nucleotide site per year	Amino acid changes per amino acid site per year
H1N1	1934–1957	24	3.9×10^{-3}	5.3×10^{-3}
H1N1	1977–1996	146	2.7×10^{-3}	4.2×10^{-3}
H3N2	1968–1996	340	3.7×10^{-3}	4.1×10^{-3}
B	1940–1996	168	1.2×10^{-3}	1.1×10^{-3}

parallel laboratory studies are essential to define influenza-related morbidity. Many methods have been used for estimating the impact of influenza illnesses in a community or country, including prospective surveillance of illnesses and influenza infections in all members of a defined population. Regular interviews of a randomly selected population to detect all symptomatic respiratory illnesses, coupled with laboratory studies to detect symptomatic and asymptomatic influenza infections, provide the most precise measurement of age-specific influenza morbidity and rates of asymptomatic infection. A number of these community- and family-based studies have been carried out during pandemic and interpandemic influenza outbreaks (Foy et al. 1976; Hall et al. 1971, 1973; Jennings and Miles 1978; Jordan et al. 1958; Monto and Ullman 1974; Philip and Bell 1961). These studies have shown that influenza epidemics disrupt school attendance and work productivity, place heavy demands on health care systems, and result in morbidity and mortality among high-risk populations almost every year.

During average epidemics overall infection rates are estimated to be 10–20 percent, but in selected populations or age groups, attack rates of 40–50 percent are not unusual. It is apparent from studies conducted during both pandemic years and interpandemic periods that age-specific attack rates are highest in school children (Glezen 1996). This correlates well with the observation that school absenteeism is followed by employee absenteeism during influenza epidemics. Elderly people are often admitted to hospital during the latter part of the epidemic. Both type A and B influenza viruses are important causes of respiratory infection within nursing homes and other long-term care facilities.

MORTALITY

One of the hallmarks of influenza is the increase in mortality during pandemics and many epidemics. William Farr (1885) is credited with developing the concept of 'excess mortality', i.e. the number of deaths observed during an epidemic of influenza-like illness in excess of the number expected. Estimating influenza-associated excess mortality provides one of the most objective measures of the severity of influenza epidemics and pandemics. Methods for determining the baseline or expected number of deaths for the winter season in the absence of an influenza epidemic have changed over the years. Various statistical approaches, ranging from a moving average to cyclical regression models and autoregressive integrated moving average (ARIMA) time series analyses have been used to calculate the baseline and threshold values (Choi and Thacker 1982; Collins and Lehmann 1951; Lui and Kendal 1987; Simonsen et al. 1997; Thompson et al. 2003).

Increased influenza mortality results not only from pneumonia and influenza (P and I) but also from cardiopulmonary and other chronic diseases that can be exacerbated by influenza (Collins and Lehmann 1951; Eickhoff et al. 1961). Quantification of deaths caused by influenza is complicated by the fact that information recorded on death certificates may fail to indicate that influenza was a cause of death because a laboratory diagnosis was not made or because influenza was not listed as a primary underlying or contributory cause of death. Therefore, calculations of influenza-associated excess mortality are based both on excess deaths from P and I as well as from all causes. Although excess mortality occurs primarily in elderly people, it can occur in all age groups, particularly among individuals who are at increased risk for complications of influenza. Excess mortality has been documented during circulation of both type A and B influenza viruses, but has been associated most often with circulation of influenza A subtypes H2N2 and H3N2. Since 1986, excess mortality in the USA has been associated most frequently with the circulation of influenza A(H3N2) viruses; ca. 90 percent of these influenza-associated excess deaths have occurred in individuals 65 or more years of age (CDC 2004).

It is estimated that >20 000 influenza-associated excess deaths occurred in the USA during each of nine different epidemics between 1972 and 1991; >40 000 influenza-associated deaths occurred during each of three of these epidemics (Simonsen et al. 1997) (Table 4).

ANTIGENIC SHIFT AND ITS IMPACT

Only influenza A viruses exhibit the second, more dramatic, kind of antigenic variation, called antigenic shift. Antigenic shift is the appearance in the human population of a new subtype of influenza A viruses containing a novel HA or a novel HA and NA immunologically distinct from isolates circulating previously. When antigenic shift occurs, the HA of the new strain

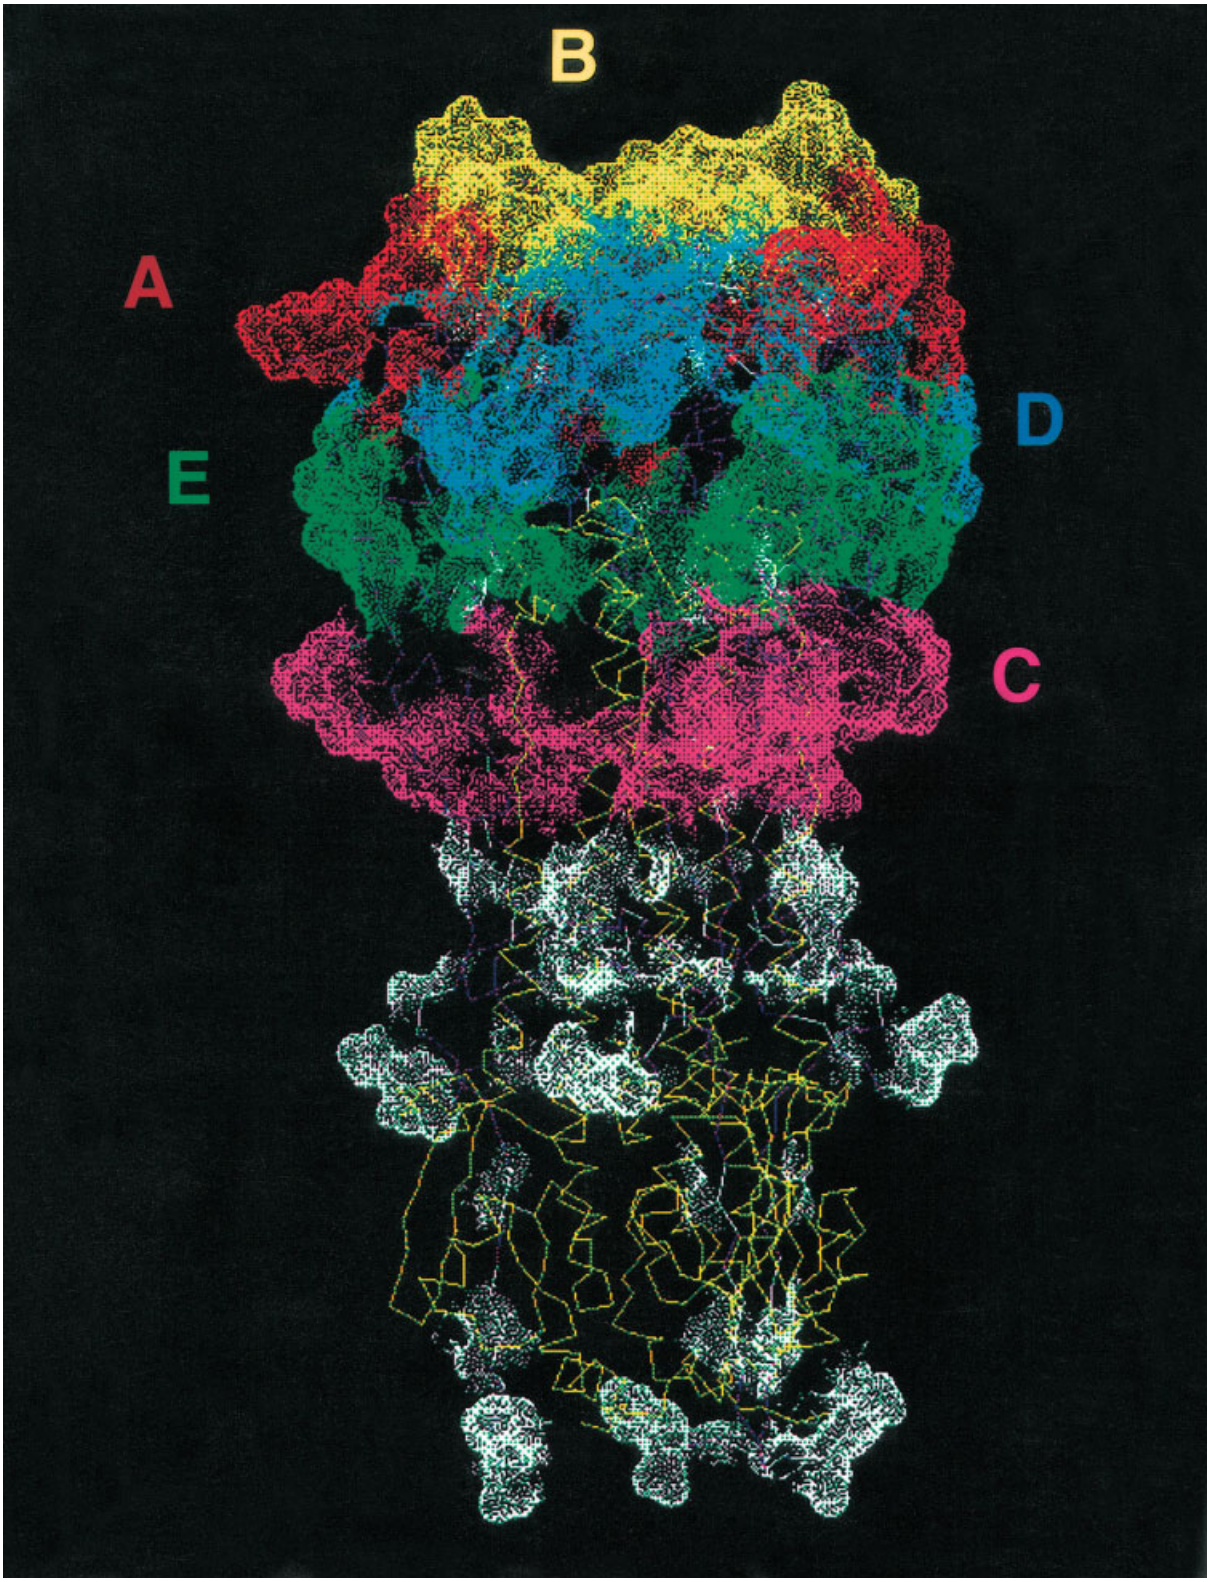

Figure 19 *Natural antigenic variation in the hemagglutinin (HA) of the H3 subtype of influenza A viruses circulating between 1968 and 1996. The HA trimer is depicted with the HA polypeptide backbone represented by an α-carbon trace in violet for the HA1 domain and in yellow for the HA2 domain. The solvent-accessible surface of residues that have changed during this period are represented by a dot surface. Antigenic regions are color coded and designated A (red), B (yellow), C (magenta), D (blue), and E (green). Amino acid residues shown in white are surface accessible but not assigned to antibody-combining sites. This graphic representation demonstrates that most of the surface-accessible amino acids in the globular head region of the HA have changed during this 28-year period of circulation in humans of influenza A(H3N2) viruses.*

Table 4 *Influenza excess mortality*

Period	Excess deaths
'Spanish' influenza	
September 1918 to April 1919	500 000
'Asian' influenza	
September 1957 to March 1969	69 800
'Hong Kong' influenza	
September 1968 to March 1969	33 800
Total	603 600
Interpandemic years	
1957–1990	600 800

would be expected to vary at the amino acid level 20–50 percent from the corresponding protein of previously circulating strains. Antigenic shift is responsible for worldwide pandemics, which occur at irregular and unpredictable intervals.

Although 16 subtypes of influenza HA have been identified in avian species, epidemics and pandemics of influenza among humans during this century seem to have been caused by viruses with HAs of only three different subtypes: H1, H2, and H3 (see Figure 1). The most severe recorded pandemic of influenza was that of Spanish influenza in 1918–1919.

Retrospective serological and genetic evidence suggests that this pandemic was caused by viruses closely related to classic swine influenza A(H1N1) virus, but its origin is unknown (Reid et al. 2004). Outbreaks of disease occurred almost simultaneously in North America, Europe, and Africa during the spring and early summer of 1918 (Crosby 1989). During the autumn of 1918 a second, more serious, wave of disease occurred. This wave peaked by the end of October but was followed by yet another wave of disease in mid-winter. Illness rates of nearly 40 percent occurred among school children during the autumn wave in the USA (Frost 1920). The differentiating features of this pandemic are the large numbers of cases with pneumonia and the unusually high case fatality rates, particularly in young healthy adults between the ages of 20 and 40 (Frost 1919). The social and medical consequences of the Spanish influenza pandemic are difficult to imagine today. About half of the 2 billion people living at that time were infected and at least 20 million of them died (Noble 1982). Hospitals were overflowing and there was a general shortage of medical services and vast disruption of community life.

Records indicate that the 1957/8 pandemic of Asian influenza A(H2N2) began in February in the southern Chinese province of Guizhou, spreading during March to Yunan province and during April to Singapore and Hong Kong (Stuart-Harris et al. 1985). The first virus isolates were obtained in Japan during May. This pandemic strain possessed completely different HA and NA antigens from the formerly circulating H1N1 viruses and spread rapidly worldwide by November 1957. Although H2N2 viruses were first isolated in the UK and the USA in June or July of 1957, peak incidence of the disease did not occur until October. This first wave of disease in both countries was followed by a second in January 1958; both waves were accompanied by excess mortality, primarily in the elderly. The timetable of key events for the pandemic of Asian influenza shown in Table 5 illustrates the short time frame for response to this pandemic and the missed opportunities for immunization after the first wave of disease. The highest attack rates during this pandemic were >50 percent in children aged 5–19 (Glezen 1996). Total influenza-associated excess mortality in the USA during this pandemic was estimated to be 69 800 (Noble 1982).

Viruses causing the Hong Kong H3N2 pandemic were first isolated in Hong Kong in July 1968. These viruses had a different HA antigen but shared the N2 NA antigen with the previously circulating Asian viruses. Widespread disease with increased excess mortality was observed in the USA during the winter of 1968/9, but in many other countries, including the UK, this did not happen until the winter of 1969/70 (Stuart-Harris et al. 1985). Total influenza-associated excess mortality in the USA for this pandemic was estimated to be 33 800 (Noble 1982).

In May 1977 the first outbreaks of disease caused by re-emerging influenza A(H1N1) viruses were observed in Tientsin, China (Kung et al. 1978). The H1N1 virus spread to other parts of Asia and reached Russia by November. Spread to Europe, North America, and the southern hemisphere followed. Illness occurred almost exclusively among people less than 20 years of age and the highest attack rates of >50 percent were among school children. These viruses were antigenically and genetically similar to H1N1 viruses that had circulated widely during the early 1950s (Kendal et al. 1978; Nakajima et al. 1978). The absence of morbidity in people over 20 years of age has been explained by the fact that they were infected with similar viruses during the 1950s. Some experts have suggested that these H1N1 viruses may have been 'genetically frozen' in nature, while others have speculated that these viruses may have accidentally escaped from a laboratory; the source remains unknown.

Although antigenic shift seems to have been a requirement for the appearance of true pandemic influenza, the emergence of influenza A viruses of a new subtype in humans does not necessarily result in a pandemic (Dowdle and Millar 1978).

Ecology of influenza

The term influenza was used to describe a variety of acute respiratory and other diseases of a number of animal species, especially horses (see section on Histor-

Table 5 *Timetable of events for the Asian influenza pandemic of 1957/58*

Date	Event
February 1957	Outbreaks of influenzalike illness in Guizhou Province, China
Early March 1957	Outbreaks of influenzalike illness in Yunan Province, China
Mid March 1957	Outbreaks widespread in China
April 1957	Outbreaks in Hong Kong, Singapore, and Taiwan
Mid May 1957	Virus isolated in Japan
June/July 1957	Virus first isolated in the USA. Outbreaks reported
September 1957	Widespread occurrence of influenza begun in the USA
October 1957	Peak incidence of disease occurred in the USA. Attack rates were highest among school children and young adults
November 1957	Incidence of disease declined in the USA. First peak of pneumonia and influenza-related deaths observed
Early December 1957	Cumulative total of 60 million doses of vaccine released in the USA; much of the vaccine was unused
January/February 1958	Second peak of pneumonia and influenza-related mortality observed with a higher proportion than usual of deaths in the elderly. It was recognized retrospectively that a second wave of disease occurred in older adults and the elderly

ical record), for many years. However, influenza A viruses have been isolated only from humans, swine, horses, cats, dogs, a variety of sea mammals, and a wide variety of both domestic and wild birds, including ducks, geese, terns, shearwaters, gulls, turkeys, chickens, quail, and pheasants (Easterday 1975; Hinshaw et al. 1980; Webster et al. 1992; Dubovi et al. 2004; Keawcharoen et al. 2004).

Studies in Asia, Australia, Europe, and North America have revealed that viruses with all 16 subtypes of HA and nine subtypes of NA have been isolated from ducks and other feral water birds (Easterday 1975; Rohm et al. 1996; Webster et al. 1992) (Table 6), an observation suggesting that avian species serve as the primary reservoir for the emergence of new pandemic strains (Webster et al. 1992). These studies have also suggested that aquatic birds are likely to be the only source for influenza viruses in other species. Infections in avian species by most influenza viruses are asymptomatic, virus replicating preferentially in cells lining the intestinal tract (Webster et al. 1978). High titers of these viruses are excreted into their water habitat by asymptomatic birds. Avirulent influenza infections in birds may be the result of influenza viruses adapting to the host over many centuries. However, a few members of the H5 and H7 subtypes can cause a lethal systemic infection owing to the susceptibility of the HAs of these viruses to cleavage in many host tissues. The large reservoir for the 16 subtypes of influenza A viruses ensures their perpetuation in nature. The avian origin of strains of influenza in humans, cats, seals, whales, pigs, horses, and domestic poultry has been documented (Webster et al. 1992; Webster and Kawaoka 1994; Li et al. 2004).

Phylogenetic studies have revealed clues that have changed our thinking about the ecology and origins of influenza A viruses of different subtypes. There are species-specific lineages of viral genes (Bean et al. 1992; Gorman et al., 1990a, b; Ito et al. 1991; Kawaoka et al. 1989), and it appears that all mammalian influenza viruses originate from the avian reservoir (Shortridge 1992; Webster and Kawaoka 1994). Besides the phylogenetic evidence supporting an avian ancestry of mammalian viruses, there is evidence from antigenic and structural studies in support of this hypothesis. Antigenic analyses of the earliest human isolate available (A/PR/8/34) suggested a direct descent from the avian-like H1N1 pandemic strain of 1918 (Brownlee and Fodor 2001). The atomic structure of the HA from the 1918 pandemic virus, A/South Carolina/1/18, has clearly revealed that the sialic acid binding pocket is very similar to that of avian influenza HA, suggesting an avian origin of this gene (Stevens et al. 2004).

Poultry, especially chickens, quail, and geese, are playing an increasingly significant role in the ecology of influenza. They are susceptible to infection with a variety of influenza subtypes from migratory waterfowl. Viral circulation in flocks, initially without causing substantial pathology, leads to the adaptation to the new species. The process of adaptation of influenza strains of the H5 and H7 subtypes to terrestrial poultry often results in acquisition of mutations at the cleavage site of the HA. These changes render the HA highly cleavable by ubiquitous proteases throughout the body which allows the virus to spread systemically. Consequently, these viruses are lethal for many bird species. The closeness of domestic poultry to human habitats and retail sales of infected live poultry have resulted in the transmission of these highly pathogenic avian viruses to humans, leading to several fatal infections in healthy children and adults (K.S. Li et al. 2004; Peiris et al. 2004; Subbarao et al. 1998).

Avian influenza H9N2 caused illness in three people in Hong Kong in 1991 and 2003, but retrospective serosurveys detected subclinical infections in the general

a) Reference strains

population (Peiris et al. 1999). The H9N2 viruses have also circulated extensively in swine herds in Asia and elsewhere. Because H9N2 viruses can readily bind sialic acid receptors present in airway epithelium of humans and other mammals, they constitute potential pandemic candidates to be monitored in surveillance programs (Matrosovich et al. 2001).

SWINE INFLUENZA

Koen (1919) reported the occurrence of an epizootic of respiratory disease among swine in Iowa, which seemed to be a new clinical entity and which co-incided with the start of the 1918 pandemic of influenza in the Midwest of the USA. Because the clinical symptoms of the disease were similar to those occurring in humans, the disease was called swine influenza. Shope (1931) demonstrated the viral cause of swine influenza in 1930, 3 years before it was shown that influenza is a viral infection in people. Retrospective serological studies in humans (Davenport et al. 1953) and subsequent investigations (reviewed by Stuart-Harris et al. (1985)) provided strong circumstantial evidence that the Shope strain was antigenically close to the virus responsible for the 1918 pandemic of Spanish influenza.

The North American Swine influenza A subtype H1N1 viruses spread from the US to Europe in 1976 (Nardelli et al. 1978). This lineage was replaced in 1979 by another H1N1 virus that had been introduced from birds into pigs (Pensaert et al. 1981). Swine influenza strains are enzootic in pig populations in many parts of the world and have also infected turkeys in the USA (Hinshaw et al. 1983a).

A number of cases or outbreaks attributable to swine H1N1 virus transmission from ill swine to people have been documented, and each is connected with concern

stemming from the association of swine disease and antibodies to swine influenza viruses with the 1918 Spanish influenza pandemic. This concern is best exemplified by the swine influenza immunization campaign that was begun in the USA after a swine influenza virus (A/New Jersey/8/76) was isolated from a young military recruit who died of pneumonia (Goldfield et al. 1977).

Serological evidence suggested that this virus was antigenically similar to the viruses believed to have caused the 1918 pandemic and that the virus had spread to other recruits (Dowdle and Millar 1978). Since that time, additional fatal cases of swine H1N1 influenza in humans have been documented, but these viruses have so far shown a limited capacity to spread in humans.

Swine influenza virus is one of the most common causes of respiratory disease in swine, and serological surveys in the USA have indicated that nearly half of the herds have antibody against this virus. Clinical evidence indicates that influenza A strains vary in the severity of disease that they cause in infected swine. The relative prevalence of different influenza A viruses in swine varies throughout the world, but it is clear that a large reservoir of influenza A viruses exists in pigs worldwide.

Critical to the hypothesis that pigs may play a crucial role in the emergence of new pandemic strains of influenza is the observation that swine are susceptible to infection by swine, avian, and human influenza viruses (see section on Receptor binding). This susceptibility to a variety of subtypes of influenza viruses provides the opportunity for genetic reassortment in swine. These findings underscore the possible role of swine as a 'mixing vessel' for the emergence of novel influenza strains (Scholtissek et al. 1985). Furthermore, classic A(H1N1) swine viruses, avian A(H1N1) viruses, and human A(H1N1) (H3N2), and type C influenza viruses have all been isolated from naturally infected swine. Avian–swine influenza reassortants were first detected in Europe in 1979 (Scholtissek et al. 1983) and continue to circulate in pigs in that part of the world. Human–avian H3N2 viruses emerged between 1983 and 1985 in Italy and have been isolated repeatedly from pigs in Europe (Webster et al. 1992).

Human H3N2 influenza entered the North American swine herds around 1995 and gave rise to double-reassortants with classical swine influenza genes in which the surface and PB1 protein genes are of human origin. These reassortants later acquired two avian internal protein genes (PA and PB2) in addition to the human and swine genes seen in the double reassortant (Zhou et al. 1999). These triple reassortants became widespread in 1998 and have circulated widely in the pig population since then (Webby et al. 2000). Experimental infection of pigs with avian viruses representing 13 of the 16 HA subtypes has also been reported (Kida et al. 1994).

DIAGNOSIS

A number of techniques have been developed for the diagnosis of influenza virus infections. Virus isolation in cultured cells or in fertilized hens' eggs or demonstration of a four-fold or greater rise in specific antibodies between acute and convalescent sera are techniques that have been used for many years. More recently, detection of viral antigens directly in clinical specimens by immunological methods and detection of viral nucleic acids by hybridization or using polymerase chain reaction (PCR) has greatly increased the speed of laboratory diagnosis.

Virus isolation and propagation

Embryonated hens' eggs, a number of primary tissue culture systems and continuous cell lines such as Madin–Darby canine kidney (MDCK; American Type Culture Collection, Rockville MD) cells can be used to isolate and grow influenza viruses for identification or research purposes. Recognition that proteolytic cleavage of the HA is necessary for viral infectivity and that inclusion of trypsin in the tissue culture fluid cleaves the HA expanded the culture systems available for influenza isolation and propagation. Replication of influenza viruses in all of its laboratory hosts is often detected by agglutination of erythrocytes added to culture fluid or by hemadsorption of erythrocytes to infected cells. On initial passage in eggs or tissue culture, some influenza viruses preferentially agglutinate guinea-pig over chicken erythrocytes, but on continued passage the viruses may preferentially agglutinate erythrocytes from chickens (Burnet and Bull 1943).

ISOLATION IN EMBRYONATED EGGS

Soon after the first identification of human influenza A viruses, Burnet (1936) reported that embryonated hens' eggs could serve as a host system for their propagation. This host system is still used for vaccine production and for generating large quantities of influenza virus that are occasionally necessary for research. To isolate both type A and type B influenza viruses, clinical samples are inoculated into the amniotic and allantoic cavities of 10–11-day-old embryonated hens' eggs. The eggs are usually incubated at 33–34°C for 2–3 days before the virus is harvested. Most type A and B influenza viruses that are originally isolated in eggs will grow well in the allantoic cavity after one or two passages. Type C influenza viruses, on the other hand, grow only in the amniotic cavity and are best propagated in 7–8-day-old embryonated hens' eggs after 5 days' incubation.

ISOLATION IN TISSUE CULTURE

Primary cynomolgus or rhesus monkey kidney cells (PMKC) are susceptible to a variety of respiratory viruses, including influenza viruses. Disadvantages with

these cells include their cost and the presence of spumaviruses. Influenza A, B, and C viruses can also be isolated in the MDCK cell line in the presence of trypsin. Primary monkey kidney and MDCK cells are most often used for the primary isolation of influenza viruses from humans.

Influenza virus isolation is still used in many laboratories worldwide. When performed correctly with properly collected specimens along with good quality laboratory cells and reagents, this method is highly sensitive. The shell vial tissue culture isolation method combines rapid detection of virus in the inoculated cells after 48–72 h, increased sensitivity being obtained by centrifugation of specimens onto the cells. Monoclonal antibodies are often used for immunofluorescent detection of viral antigens in the inoculated cells (Kalin and Grandien 1993). Obtaining isolates for further antigenic and genetic characterization is an essential part of worldwide surveillance for the emergence of significant antigenic variants of influenza. Detection of these new variants may signal the need to revise the formulation of the influenza vaccine or to recommend other measures for public health control.

Serology

Serology may establish that infection by influenza viruses has occurred when the virus is not detected by any other method. Serological tests include complement fixation (CF), hemagglutination inhibition (HAI), neutralization, and enzyme immunoassays (EIA). These techniques are the fundamental tools in epidemiological and immunological studies as well as in the evaluation of the immunogenic properties of the vaccine.

The CF test measures antibodies against the NP and thus allows type-specific detection of antibodies to type A and B influenza viruses rather than a subtype- or strain-specific diagnosis. This test is relatively insensitive in detecting rises in pairs of serum titers from individuals with a recent infection, but can be used when more specific reagents are not available. HAI and neutralization are more sensitive and measure antibodies against subtype- and strain-specific antigens. EIA tests can be configured according to the nature of the antigens and the isotype of immunoglobulin chosen for the assay (Ziegler et al. 1995).

The HAI test is the serological test most often applied to influenza viruses (Figure 20). Because of the instability of HA, the dilution of antigen used must be precisely determined by HA titration each time the HAI test is performed. The test is also complicated by the presence in sera of several species of nonspecific inhibitors of hemagglutination. These inhibitors interact with the HA molecule and prevent the agglutination of erythrocytes, even in the absence of specific antibodies. The non-specific inhibitors fall into three classes: α inhibitors, which are present in human serum and are heat-stable sialylated glycoproteins that inhibit hemagglutination but do not neutralize viral infectivity; β inhibitors, which are also present in human serum and but are heat-labile and have neutralizing activity; and γ inhibitors, which are present in horse serum and are heat-stable sialylated sialoproteins with neutralizing activity. The α and γ inhibitors function as receptor analogues by competing with red cell receptors for binding to HA. Removal of nonspecific inhibitors from sera by using receptor-destroying enzyme or periodate is an essential step in the HAI test (Kendal et al. 1982). In addition, interference by antineuraminidase antibody and variability of viruses in avidity for red cells and antibody can influence the test results.

Rapid virus diagnosis

POINT-OF-CARE TESTS

The availability of influenza antiviral drugs has increased both physician and patient demand for rapid diagnosis. Rapid EIAs for influenza A and influenza B viruses which produce a result in 15 to 20 min are commercially available (Johnston and Bloy 1993; Ryan-Poirier et al. 1992; Todd et al. 1995; Waner et al. 1991). A positive result can be obtained with as few as 20 influenza virus-infected cells or 2 000 infectious virus particles. There currently are many commercially available point-of-care tests that rely on antigen detection in clinical specimens. Most of the tests use an immunoassay method to detect viral NP antigen, while one uses an enzyme-based chromogenic indicator to detect the presence of viral NA. These tests have a sensitivity of 50 to 100 percent and a specificity of 50 to 100 percent according to the manufacturers. Variation in sensitivity and specificity may depend on the study design, the type of sample collected, the timing of sample collection, the age of the patient, and other factors. Such tests show promise in certain clinical settings; however, the sensitivity and specificity of these tests under field conditions may be lower than reported in the published controlled studies. Furthermore, the positive predictive value of these tests may be quite low early in the influenza season, when influenza infections are relatively rare. All of these tests are less sensitive and specific than more traditional laboratory diagnostic methods such as virus isolation and serological diagnosis by the HI test, but they allow a test result to be obtained in time to treat the patient. These tests are useful in clinical laboratories of hospitals and nursing homes to detect institutional influenza outbreaks. However, because both false-positive and false-negative results are reported frequently for these point-of-care rapid tests, it is important to test multiple samples from the same outbreak before making decisions about treatment or prophylaxis for institutionalized patients.

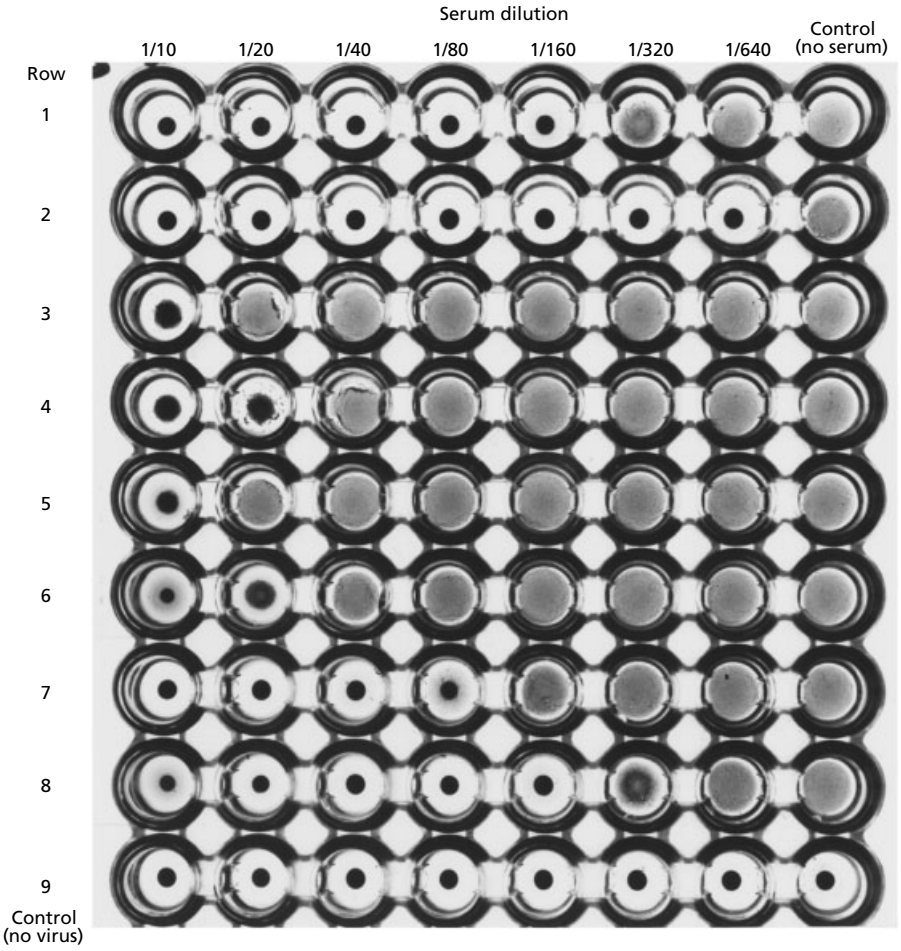

Figure 20 *Hemagglutination inhibition (HAI) test for influenza antibodies. The HAI is a competitive test in which antibodies present in an immune serum compete with red blood cells to bind the viral hemagglutinin. Row 1 shows results when antibodies are present and virus-induced hemagglutination of erythrocytes is inhibited with a consequent formation of erythrocyte 'buttons.' Row 3 shows results obtained when antibody is not present to inhibit viral hemagglutination.*

MOLECULAR METHODS

Molecular methods are being applied more widely in the diagnosis of influenza virus infections as well as in the characterization of influenza virus isolates. Molecular techniques are likely to supplant virus culture as the 'gold standard' for virus detection because they are more sensitive and offer advantages of speed and more precise characterization over other, more traditional laboratory methods. Abundant sequence data derived from isolates collected over several decades and from many geographic regions are available for selecting conserved target sequences to allow the identification of all isolates within a subtype, to discriminate between subtypes, and to distinguish between strains within a subtype. The genetic analysis of a large number of influenza viruses isolated throughout the world each year provides information for a timely update of vaccine strains and of molecular reagents for diagnosis. With currently available technology, updating molecular probes is more rapid and practical than updating MAbs on a regular basis.

For reverse transcriptase polymerase chain reaction (RT-PCR), viral nucleic acids are extracted from clinical specimens, allantoic fluid of embryonated hen eggs, or cell culture material by using the guanidium thiocyanate method (Boom et al. 1990) or commercial kits. cDNA is synthesized by in vitro reverse transcription of viral RNA primed either by specific synthetic oligonucleotides matching known nucleotide sequences on the viral genes or by random hexamers. This cDNA is amplified with specific primers and DNA polymerase. Finally, the amplified product is detected by any of numerous methods developed for this purpose.

Use of RT-PCR amplification of influenza virus RNA to diagnose influenza has been reported by Zhang and Evans (1991), Claas et al. (1992, 1993), Ellis et al. (1997a), Stockton et al. (1998), and Wright et al. (1995). Wright and colleagues developed a multiplex RT-PCR for type- and subtype-specific identification of currently circulating human influenza viruses. Three sets of oligonucleotide primers were used to identify the *NP* gene of influenza A viruses, the *NS* gene of influenza B viruses,

the *HA* genes of influenza A subtypes H1 and H3, and the *NA* gene of influenza A subtypes N1 and N2. A type- and subtype-specific multiplex nested RT-PCR format was evaluated on 619 specimens collected during the 1995 to 1996 influenza season in England (Ellis et al. 1997a).

The superiority of RT-PCR over virus culture recently has been reported in several studies (Boivin et al. 2001; Cherian et al. 1994; Ellis et al. 1997a; Herrmann et al. 2001; Kehl et al. 2001; Plakokefalos et al. 2000; Zambon et al. 2001). Nested RT-PCR and similar primers were used for most of these studies. Conserved matrix gene primers were used for typing samples as influenza A or B virus, and primers designed for detecting the HA and NA genes were used for subtyping influenza A virus specimens. In the largest of these studies, data were available for 1 033 patients; of these, 730 patients were positive by RT-PCR, 629 were positive by serological testing, and 579 were positive by virus culture (Zambon et al. 2001). RT-PCR is a useful method for rapidly processing large numbers of clinical isolates for influenza diagnosis in centralized laboratories that have sufficient resources and expertise.

A new approach to influenza diagnosis is to use DNA microarrays containing nucleic acid probes for typing and subtyping influenza viruses and to identify common respiratory viral pathogens such as influenza A, B, and C viruses, respiratory syncytial virus, parainfluenza viruses, and adenoviruses. One study demonstrated that a model microarray containing multiple probes derived from cloned PCR-amplified fragments of influenza A and B virus matrix, HA, and NA genes correctly identified complementary influenza virus-specific DNA (J. Li et al. 2001). Although more extensive studies are needed, microarray technology appears to hold future promise for rapid and accurate diagnosis and large-scale surveillance.

PCR combined with endonuclease restriction analysis has been applied to the genetic characterization of influenza viruses. For this technique, oligonucleotide primers are designed to amplify a product that contains unique restriction enzyme cleavage sites. This method can discriminate between two lineages of influenza A (H3N2) viruses which circulated simultaneously during an influenza season (Ellis et al. 1997b; Zou 1997); can determine the genetic stability of cold-adapted, reassortant live vaccine strains (Klimov and Cox 1995); and allows the rapid identification of drug-resistant influenza virus isolates (Klimov et al. 1995).

CONTROL

The morbidity and mortality caused by influenza virus infections and the disruptive effects of epidemics and pandemics on the community justify strenuous efforts to prevent this disease. Two measures are currently available to reduce the impact of influenza: immunoprophylaxis with influenza vaccines and chemoprophylaxis, or therapy with the antiviral drugs. Research to develop additional influenza vaccines and antiviral agents may result in additional products for the prevention and control of influenza.

Immunization

Vaccination is currently the most effective measure for reducing the impact of influenza. Immunization is focused mainly on individuals at increased risk of complications of influenza infection and on individuals who might transmit influenza to such people (CDC 2004; Fedson et al. 1995; Nicholson et al. 1995). For example, influenza vaccine is currently strongly recommended in the USA for anyone $\geqslant$6 months of age who, because of age or an underlying medical condition, is at increased risk for complications of influenza. They include people $\geqslant$65 years of age; people in residential or nursing homes; those with chronic disorders of the pulmonary or cardiovascular systems, including children with asthma; children aged 6–23 months; women who will be pregnant during the influenza season; anyone who has required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications); and children and teenagers (6 months to 18 years of age) who are taking aspirin in the long term and may be at risk of developing Reye syndrome after influenza. People who should receive vaccination to reduce the likelihood of transmission to high-risk groups include: physicians, nurses, and other personnel in both hospital and outpatient care settings; staff, visitors, and volunteers in residential and nursing homes; providers of home care to individuals at high risk and household members (including children) of such people.

Vaccination is generally considered safe for anyone who can eat foods containing egg. Hypersensitivity to hens' eggs, the substrate for vaccine production, is the only contraindication. Desensitization to eggs followed by vaccination can be considered for individuals in high-risk groups.

VACCINE FORMULATION

Each February the World Health Organization makes recommendations concerning the antigenic properties of the strains of influenza that are to be used in vaccines during the following influenza season. These recommendations are based on data gathered by the four World Health Organization (WHO) Collaborating Centers (Atlanta, USA; London, UK; Melbourne, Australia; and Tokyo, Japan) together with data gathered by many national WHO collaborating laboratories. The objective

Table 7 *Influenza vaccine strains recommended by WHO, 1987/8 to 2004/5 for the northern hemisphere*

Year	H1N1	H3N2	B
1987/8	A/Singapore/06/86-like[a]	A/Leningrad/360/86-like	B/Ann Arbor/1/86-like

a) Most countries used the antigenically equivalent A/Taiwan/1/86 virus.
b) Most countries used the antigenically equivalent A/Texas/36/91 virus.
c) Most countries used the antigenically equivalent A/Shanghai/16/89 virus.
d) Most countries used the antigenically equivalent A/Nanchang/33/95 virus.
e) Most countries used the antigenically equivalent B/Harbin/7/94 virus.
f) Most countries used the antigenically equivalent B/Yamanashi/166/98 virus.
g) Most countries used the antigenically equivalent A/Panama/2007/99 virus.
h) Most countries used the antigenically equivalent B/Jiangsu/10/2003 or B/Jilin/20/2003 virus.
i) Most countries used the antigenically equivalent A/Wyoming.

is to match the antigenic properties of the HA and NA of the recommended vaccine strains as closely as possible with those of strains that are emerging and are likely to circulate the following winter.

Three types of data are used to make the WHO influenza vaccine strain recommendations each year. First, data are obtained from reference antigenic and genetic analyses of influenza viruses isolated through WHO's global influenza surveillance network. These data are used to detect new antigenic variants that might have emerged since the previous recommendations were issued and to determine how these variants are genetically and antigenically related to other circulating strains. Second, epidemiological and virological data are combined to determine whether newly identified variants are detected in association with outbreaks of disease in multiple locations or are associated only with a single case or a few sporadic cases. Third, the ability of the existing vaccine strains to induce an antibody response in humans to the newly detected variants is examined. These three types of data are combined to determine what new antigenic variants are circulating, whether these variants are associated with significant disease, and whether immunization with the existing vaccine could protect against disease caused by the new variants.

Influenza vaccines in recent years have been trivalent, containing strains of the two influenza A subtypes that are circulating along with a representative type B strain (Table 7). Viruses used by vaccine manufacturers for the type B component of the vaccine are naturally occurring virus strains that replicate to relatively high titers in the allantoic cavity of embryonated hens' eggs. The strains most often used for the type A components are high-growth reassortant viruses that contain internal genes that specify the property of high growth in eggs derived from the A/PR/8/34(H1N1) laboratory adapted strain together with the surface glycoproteins, HA and NA, from the recommended field strain. Vaccine strains are grown individually in the allantoic cavity of embryonated hens' eggs and then purified and concentrated by zonal centrifugation or column chromatography and finally inactivated with formalin or other chemicals. Vaccines are routinely standardized by means of single radial diffusion tests (Wood et al. 1981) to contain 15 μg HA per virus strain per dose; the quantity of NA is not standardized and may vary between vaccines.

Influenza vaccines currently in use are live-attenuated vaccines or inactivated subvirion (SV), or surface antigen vaccines. Live-attenuated vaccine contains avirulent replicating virus; SV vaccine contains detergent-

disrupted inactivated virus; surface antigen vaccines contain isolated HA and NA proteins (CDC 2004). Although current viruses are still produced by growing viruses in the allantoic sac of embryonated hens' eggs, numerous refinements have improved the immunogenicity and reactogenicity of current inactivated vaccines; they include the use of zonal centrifugation, the use of ether or other lipid solvents to disrupt the virus, the introduction of high-yield reassortants to improve yields, and the development of better methods to quantify the amount of viral antigens present in the vaccines. Thus modern influenza vaccines are associated with minimal side effects. Up to one-third of inactivated vaccine recipients may feel some discomfort at the vaccination site for up to 2 days after vaccination; only about 1–2 percent have fever, malaise, myalgia, or other systemic reaction, which may begin 6–12 h after vaccination and persists for 1–2 days (Betts 1995; CDC 2004).

EFFECTIVENESS OF INACTIVATED INFLUENZA VACCINES

Inactivated parenterally administered influenza vaccines have been in use since the 1940s. A large number of trials in both military and civilian populations have demonstrated the efficacy of inactivated vaccines in the prevention of naturally occurring outbreaks of influenza A(H1H1), (H2N2), and (H3N2) viruses (Ada et al. 1987; Couch et al. 1986; Dowdle 1981; Monto and Terpenning 1996). The large variations in vaccine efficacy and clinical effectiveness reported in the literature are due to differences in the ages and immunocompetence of the vaccine recipients, the degree of antigenic similarity between the vaccine and circulating virus strains, the vaccine potency, the extent and intensity of transmission of influenza, and other respiratory viruses circulating during the study period, as well as the surveillance and laboratory methods used for the studies. Current inactivated vaccines protect 70–90 percent of normal healthy adult recipients against naturally occurring disease when the antigens of the vaccine and those of the circulating influenza viruses are closely related. In people >65 years of age (a group that is a primary target of vaccination programmes in a number of countries), the antibody response to HA is reduced and clinical effectiveness of vaccine is lower. This is probably a reflection of reduced immunocompetence (Ershler et al. 1984). For older people living in the community, the effectiveness of influenza vaccine in preventing hospitalization for P and I ranges from 30 percent to 70 percent. Among elderly people living in nursing homes, inactivated vaccines confer less protection against illness than in younger healthy individuals; they are more effective in preventing severe illness or secondary complications requiring hospitalization (50–60 percent) and death (80 percent) than in protecting against disease (30–40 percent) (CDC 2004).

Chemotherapy

The chemically related drugs amantadine and rimantadine hydrochloride interfere with the replication cycle of all subtypes of type A but not type B influenza viruses (Hayden 1996; Van Voris and Newell 1992). Amantadine and rimantadine, its α-methyl derivative, share mechanisms of action, antiviral spectrums, oral bioavailability, prolonged plasma half-life, and clinical efficacy. Both drugs inhibit the replication of influenza A viruses at low, clinically achievable concentrations of <1 μg/ml (Tominack and Hayden 1987), but concerns about side-effects involving the central nervous system have limited the use of amantadine.

Amantadine and rimantadine are 70–90 percent effective in preventing illness caused by naturally occurring strains of type A influenza viruses when administered prophylactically to healthy adults or children when influenza viruses are circulating. These drugs can also reduce the severity and duration of illness caused by influenza A viruses when administered within 48 h of onset of symptoms.

The antiviral activity of both of these compounds is exerted through interference with two different ion channel functions of the viral M2 protein (see section entitled M2). The first involves inhibition of the acid-mediated dissociation of the matrix protein from the RNP complex within endosomes early in replication; this dissociation is essential for initiating viral replication (Pinto et al. 1992; Sugrue et al. 1990a). A second effect on virus maturation relating to a low pH-mediated alteration of the HA protein during its transport to the cell surface occurs during the replication of certain avian influenza viruses (Ohuchi et al. 1994; Sugrue et al. 1990a; Takeuchi and Lamb 1994).

Influenza A viruses are cross-susceptible and cross-resistant to amantadine and rimantadine. Viral strains responsible for pandemics and epidemics in recent years have all been drug-sensitive (Hayden 1996), but resistance to these compounds is readily selected by growth in the presence of these drugs either in vivo or in vitro. Resistance is associated with single nucleotide changes in RNA segment 7 and corresponding amino acid substitutions at one of four sites (amino acids 26, 27, 30, and 31 for human influenza A viruses) in the transmembrane region of the M2 protein (Hay 1992). Resistant viruses can emerge when either of these drugs is administered for treatment in adults or children. Although the frequency of the emergence of resistance is not firmly established, resistant variants have been recovered from ca. 30 percent of treated children or adults (Hall et al. 1987; Hayden et al. 1989). Nevertheless, treated individuals who shed resistant viruses recover rapidly and the duration of shedding is relatively short, so the clinical significance of the emergence of resistance in an individual is unclear. Apparent transmission of resistant virus

associated with failure of drug prophylaxis has been documented in nursing home residents receiving amantadine and in household contacts of rimantadine-treated individuals (Degelau et al. 1992; Hayden et al. 1989; Houck et al. 1995; Mast et al. 1991). Resistant viruses seem to be pathogenic and can cause typical influenza, but resistant viruses are no more transmissible or virulent than strains sensitive to amantadine and rimantadine (Hayden 1996).

Neuraminidase inhibitors

Multi-cycle replication of influenza virus in the host requires an active neuraminidase on the virus particles (see Table 2 and NA section). Zanamivir and oseltamivir are chemically related drugs known as neuraminidase inhibitors that have antiviral activity against both influenza A and B viruses (Hayden 1999, 2000). Both zanamivir and oseltamivir are approved for treating uncomplicated influenza infections. Zanamivir is approved for persons aged $\geqslant$7 years, and oseltamivir is approved for patients aged $\geqslant$1 year. Oseltamivir is administered orally, whereas zanamivir is for inhalation. When administered within 2 days of illness onset to otherwise healthy adults, zanamivir and oseltamivir can reduce the duration of uncomplicated influenza A and B illness by approximately 1 day, compared with placebo (Hayden et al. 1997; Makela et al. 2000; Demichelli et al. 2000). The course of oseltamivir therapy for persons with influenza A illness is 5 days. Oseltamivir is the only drug that has been approved for prophylactic use, being restricted to persons aged $\geqslant$13 years (Monto et al. 2002). Up to 82 percent of febrile, laboratory-confirmed influenza illnesses were prevented by oseltaminvir prophylaxis (Hayden et al. 1999; Monto et al. 1999). Besides their traditional use for the currently circulating strains of influenza A and B, neuraminidase inhibitors could prove critical to protect the health of the population at risk of infection by an emerging pandemic strain of influenza virus, until a suitable vaccine becomes available.

Emergence zanamivir and oseltamivir-resistant variants can be induced in influenza A and B viruses in vitro, but induction of resistance requires multiple passages in cell culture (Gubareva et al. 1997). Development of viral resistance to zanamivir and oseltamivir during treatment has been identified but does not appear to be frequent, with children providing a higher yield of resistant variants (Kiso et al. 2004; McKimm-Breschkin 2003). Available diagnostic tests are not optimal for detecting clinical resistance to the neuraminidase inhibitor antiviral drugs, but new diagnostic tests may revert this situation (McSharry et al. 2004). Coordinated surveillance activities that have been conducted since 1999 to detect the emergence of neuraminidase resistant variants provide the necessary information regarding the continuity of drug efficacy (Zambon and Hayden 2001).

Replication	3		

This chapter provides a general overview of the structure and replication of viruses in the family *Paramyxoviridae*. Subsequent chapters describe each group of viruses in greater detail including the diseases associated with these viruses.

CLASSIFICATION

The family *Paramyxoviridae* includes several important human pathogens, as well as viruses affecting various species of mammals, birds, and reptiles. Together with the families *Rhabdoviridae* and *Filoviridae* they form the order *Mononegavirales*. Members of this order have a nonsegmented, single-stranded, negative-sense RNA genome, a conserved gene order, and similar replication strategy. Paramxyoviruses are pleomorphic, enveloped viruses that contain helical nucleocapsids and replicate in the cytoplasm of infected cells. The family is divided into two subfamilies, *Paramyxovirinae* and *Pneumovirinae*, which are distinguished by the diameter and pitch of their nucleocapsids, the number of genes and the presence or absence of a modified transcript of their phosphoprotein (*P*) genes. Several new genera have been added to the family over the past few years. At present, the subfamily *Paramyxovirinae* contains five genera, while the *Pneumovirinae* contains two (Mayo 2002). Viruses representing each of the subfamilies and genera are listed in Table 1. Members of the same genus share antigenic cross-reactivity and a higher degree of nucleotide sequence similarity. Distinguishing features of the genera in the subfamily *Paramyxovirinae* include the presence or absence of hemagglutination and neuraminidase activity, the length and conservation of intergenic regions, and the organization and coding capacity of the *P* gene. The two genera of the subfamily *Pneumovirinae* are characterized by the presence or absence of the *NS1* and *NS2* genes and their gene order (Table 2, Figure 1).

A number of new paramyxoviruses have been isolated recently, but have not yet been assigned to a genus. Sixteen paramyxovirus isolates from reptilian species (Ahne et al. 1999) have been described; the archetype is fer-de-lance virus (Kurath et al. 2004), which has been completely sequenced. This virus has a novel gene located between the *N* and *P* gene, which has no counterpart in any of the other viruses of the family. A number of paramyxoviruses has been isolated from rodents, including Nariva virus and Mossman virus (Roos and Wollman 1979; Miller et al. 2003). Tupaia virus was discovered in a cell line derived from tree shrews (Tidona et al. 1999) and Salem virus was isolated from horses (Renshaw et al. 2000). The natural distribution and pathogenic potential of these viruses are mostly unknown.

MORPHOLOGY AND GENERAL PROPERTIES

Paramyxoviridae are pleomorphic viruses with lipid envelopes derived from the plasma membrane of the

infected cell (Klenk and Choppin 1969, 1970). Virus particles range from 150 to 400 nm in diameter and are generally spherical, but can also be filamentous. The virions contain two viral transmembrane glycoproteins that appear as spikes of varying length on electron micrographs. The envelope surrounds the nucleocapsid, which consists of the RNA genome encapsidated by the viral nucleoprotein. Nucleocapsids of *Paramyxovirinae* measure 18 nm in diameter, with a pitch of about 5.0 nm. The nucleocapsids of the *Pneumovirinae* are more slender, with a diameter of 13–14 nm and a pitch of 6.5–7.0 nm (Compans and Choppin 1967a,b; Finch and Gibbs 1970).

Paramyxoviruses are transmitted via close contact or the airborne (droplet or aerosol) route. The two transmembrane glycoproteins serve as attachment and fusion proteins. After attachment to a receptor on the surface of the host cell, fusion of the virion envelope and the host-cell membrane takes place at neutral pH. Fusion can also occur between infected and neighboring uninfected cells, resulting in the characteristic cytopathic effect of syncytium formation in cell culture or the appearance of multinucleated giant cells in host tissues. Cell lysis is another common outcome of infection with paramyxoviruses. In addition to the receptor-binding function, the attachment proteins of the genera *Morbillivirus*, *Respirovirus*, *Rubulavirus*, and *Avulavirus* also agglutinate red blood cells, and the attachment proteins of the latter three possess neuraminidase activities (Lamb and Kolakofsky 2001).

The density of the virus particles is 1.18–1.20 g/cm^3. Protein comprises most of the virion composition by weight (69–74 percent), lipid makes up 20–25 percent, and carbohydrate comprises 5–6 percent of the virion weight. The genomes of all paramyxoviruses are composed of single-stranded RNA with a density of approximately 1.3 g/cm^3. Reagents that disrupt lipids, such as organic solvents and detergents, as well as formaldehyde and oxidizing agents, destroy the infectious nature of the viruses. The viruses are also inactivated by ultraviolet light, heating, and drying.

GENOME STRUCTURE AND ORGANIZATION

The complete genomic sequences of representative viruses from every genus of the family are available on Genbank. Genomes of the *Paramyxoviridae* range from 15 000 to more than 18 000 nucleotides in length. Within the subfamily *Paramyxovirinae*, the gene order of *N–P–M–F–H/HN/G–L* is conserved; however, two members of the genus *Rubulavirus* and at least one member of the genus *Avulavirus* possess a gene encoding a small, hydrophobic protein (*SH*) that is located between the *F* and *HN* genes (Figure 1).

All members of the subfamily *Pneumoviridae* contain an *SH* and *M2* gene. The positions of the *SH*, *F*, *G*, and *M2* genes differ between the pneumoviruses and the metapneumoviruses (Figure 1). Furthermore, the 'normal' gene order of *F* followed by *G* is reversed in the pneumoviruses. The pneumoviruses are also unusual in that they have two additional genes, *NS1* and *NS2*, preceding the *N* gene.

The total length of the genomes (in nucleotides) of all members of the subfamily *Paramyxovirinae* is evenly divisible by six. This 'rule-of-six' proposes that one nucleocapsid protein binds to six nucleotides, and that the position of the nucleotides of certain regulatory elements within a group of six has consequences for their function (Calain and Roux 1993). The rule of six does not appear to apply to the *Pneumovirinae* (Samal and Collins 1996).

The promoters for both transcription and replication lie in the noncoding regions at the genomic termini. The leader sequence at the 3′ terminus of the genome is approximately 50 nucleotides in length for all *Paramyxoviridae* and contains promoter signals for both transcription and replication. The length of the trailer at the 5′ terminus varies between 20 and 114 nucleotides and only contains the complement of a promoter for replication. The terminal 12–13 nucleotides are very well

conserved within a genus and have a high degree of complementarity with each other.

Each gene contains *cis*-acting, noncoding regions preceding and following the open reading frame (ORF). These regions contain conserved transcriptional start and stop signals. The mRNA stop signal includes several U residues, which serve as templates for polyadenylation of the mRNAs. Within most of the genera, the intergenic regions are conserved trinucleotides. However, the rubulaviruses and the viruses in the subfamily *Pneumoviridae* have intergenic regions with lengths varying from one to 90 nucleotides, with no conservation of sequence (Hardy et al. 1999). Finally, in the morbilliviruses, there is a long untranslated region of approximately 1 000 nucleotides between the M ORF and the F ORF. A similar phenomenon is observed in the henipaviruses, where the 5′ and 3′ untranslated regions for most of the genes are longer than in those of the other paramyxoviruses, especially in the *P* gene (Harcourt et al. 2000). The functional significance of these long, noncoding regions is unknown.

REPLICATION

Attachment and penetration

Attachment of virus particles to the host-cell membranes occurs through the viral glycoprotein, which is variably called G, H, or HN, depending on the presence or absence of hemagglutination (H) or neuraminidase activity (N) (Table 2; Table 3). Respiroviruses and rubulaviruses bind to sialic acid-containing proteins or lipids, while pneumoviruses attach to glycosaminoglycans containing heparin sulfate and chondroitin sulfate (Feldman et al. 1999). In contrast, morbilliviruses bind specific receptor proteins on the cell surface. For measles virus, two receptors have been identified, CD46, a protein involved in the regulation of complement activation (Dorig et al. 1993; Naniche et al. 1993), and signaling lymphocyte activation molecule (SLAM) (Tatsuo et al. 2000). and rinderpest virus bind the canine and bovine homologues of SLAM (Tatsuo et al. 2001). Specific receptors have not yet been identified for other members of the family.

Following attachment, the fusion (F) glycoprotein mediates fusion of the viral envelope with the plasma membrane of the host cell. Fusion occurs at neutral pH and requires the co-operation of the F and G/H/HN proteins. It is postulated that engagement of the receptor triggers conformational changes in F that initiate fusion. As a result of the fusion process, the nucleocapsid is released into the cytoplasm (Lamb 1993).

Transcription and replication

Primary transcription begins immediately after release of the nucleocapsid into the cytoplasm. The viral RNA-dependent RNA polymerase complex is contained in the virion. The nucleocapsid serves as the template for RNA synthesis and does not appear to disassemble. The polymerase complex enters the negative sense genomic template at the promoter region in the 3′ leader to initiate transcription. Each gene is transcribed into a monocistronic mRNA, regulated by the transcriptional start and stop sites at the beginning and end of the gene. The transcripts are capped and methylated at the 5′ terminus and polyadenylated at the 3′ terminus by the viral polymerase complex. The template for the poly(A) tail is the short poly(U) sequence that is part of the transcription stop signal following each gene. It has been suggested that the polymerase stutters at the stop signals to synthesize poly(A) tails of the mRNAs. While in transcription mode, the polymerase pauses at the gene stop signal, traverses the intergenic region, and reinitiates transcription at the next gene start signal. During this process, some polymerase molecules disengage from the template. Since there is only a single promoter at the 3′ terminus of the genome, the disengaged polymerase molecules can reinitiate transcription only at the 3′ terminus. This process leads to a gradient of transcription, in which the genes located near the 3′ terminus of the genome are more frequently transcribed than the genes at the 5′ terminus. Thus, regulation of viral gene expression is achieved by the establishment of a message gradient (Cattaneo et al. 1987; Homann et al. 1990).

The polymerases of all members of the subfamily *Paramyxovirinae* utilize a process termed RNA editing to insert nontemplated G nucleotides at a specific site to modify some of the mRNAs transcribed from the *P* gene (Thomas et al. 1988). This process results in a shift of the reading frame, beginning at the editing site, in the edited transcripts. The resulting proteins share the same amino terminal sequences as the proteins translated from the unedited transcripts, but have unique carboxyl termini. The protein translated from the unedited

transcript is the phosphoprotein (P), while the V protein is encoded by the edited transcript. The exception is found in the rubulaviruses where the unedited transcript codes for the V protein, and the P protein ORF is only accessible through editing. The editing site is highly conserved among the *Paramyxovirinae*. By contrast, all members of the subfamily *Pneumovirinae* produce only the P protein from the *P* gene. An interesting characteristic of the human and bovine respiratory syncytial viruses is that the transcriptional start site for the *L* gene lies within the *M2* gene (Collins et al. 1987).

The translation of primary transcripts leads to the accumulation of viral proteins, and a switch from transcription to replication. In replication mode, the polymerase complex enters the same (or an overlapping) promoter in the 3′ leader sequence, but ignores all transcriptional regulatory signals to transcribe a full-length, positive-sense antigenome. This requires concomitant encapsidation of the nascent strand. It is assumed that the nascent 5′ termini contain specific nucleation sites for encapsidation, although nonspecific encapsidation of nonviral RNA has been reported for several paramyxoviruses. A promoter in the 3′ untranslated region of the new antigenome (the complement to the trailer sequence) serves as a starting point for the synthesis of new, negative-sense genomes. The production of antigenomes and genomes depends on the continuous availability of nucleoprotein. It has long been assumed that the availability of nucleoprotein regulates the switch from transcription to replication; however, there is some evidence that this is not the case (Fearns et al. 1997). New genomes can serve as templates for secondary transcription.

Virus assembly

The assembly of virus particles requires cessation of genome replication, preparation of completed nucleocapsids for packaging, and preparation of regions of the plasma membrane to accept nucleocapsids for budding. The matrix (M) proteins of Sendai virus and measles virus have been shown to inhibit viral transcription in vitro, this function may be involved in the cessation of replication (Suryanarayana et al. 1994; Ogino et al. 2003). Polymerase complexes remain associated with the packaged nucleocapsid and serve to initiate the next cycle of infection. While the nucleocapsid is assembled in the cytoplasm, the glycoproteins are synthesized in the endoplasmic reticulum and undergo maturation during their transport through the Golgi network to the cell membrane. The M protein clearly plays a role in the interaction between the nucleocapsid and the membrane, but it does not appear to be the driving force behind vesicle formation (Schmitt et al. 2002). Budding of virus particles occurs at specialized membrane locations called lipid rafts, which are characterized by a high content of cholesterol and sphingolipids. While viral glycoproteins are concentrated in lipid rafts (Manie et al. 2000), host proteins are excluded from the viral membrane. The cytoplasmic tails of the F and G/H/HN proteins play a role in interaction with the M protein (Ali and Nayak 2000), transport to cell surfaces (Parks and Lamb 1990), and association with rafts (Dolganiuc et al. 2003). The orientation of particle release from the apical membrane may depend on the interaction of M and the cytoplasmic tails of the glycoproteins (Naim et al. 2000). In Sendai virus, interaction of the M protein with the microtubule network is required for apical release of the virus (Tashiro et al. 1993, 1996).

POLYPEPTIDES

Nucleoprotein

As a result of the location of the N gene at or near the 3′ terminus of the genome, the nucleoprotein (N) is the most abundant structural protein in infected cells and virions. N proteins vary in size from 391 to 553 amino acids and play a pivotal role in virus replication. Both genomic and antigenomic RNA must be encapsidated by N to serve as template for transcription or replication. The nucleocapsid binds the polymerase complex, through interaction with the P subunit of that complex. N–N binding sites and separate sites for the interaction of soluble and assembled N with P have been mapped for several members of the family. Structurally, N proteins can be divided into a core, consisting of the amino terminal 80 percent of the protein, and a carboxyl terminal tail. While the core is relatively well conserved among members of a genus, the tail is highly variable, negatively charged and phosphorylated (Hsu and Kingsbury 1982; Curran et al. 1993; Ryan et al. 1993). Presumably the assembled N protein also interacts with the M protein during virion assembly (Coronel et al. 2001). Despite the close association of N with RNA, classic RNA-binding motifs are absent from the predicted amino acid sequences examined (Dreyfuss et al. 1993).

Phosphoprotein

Members of the subfamily *Paramyxovirinae* have evolved unique mechanisms to maximize the available coding capacity of their genes without expanding their overall genome size. These mechanisms include leaky ribosomal scanning, internal ribosomal initiation, and use of non-AUG start codons (Curran and Kolakofsky 1988). Secondly, transcriptional diversity is generated by RNA editing. In contrast, members of the subfamily *Pneumovirinae* encode only a P protein from the cognate gene, thus defining a major difference between the subfamilies.

All *Paramyxovirinae* express a P protein, although the strategy for expression varies among the genera. All genera except for the rubulaviruses express the P from unedited mRNA, while insertion of a single G residue provides access to the V ORF. In rubulaviruses, the unedited transcript codes for the V protein, and the P protein is expressed from an edited message containing an insertion of two G residues. The P proteins are the most variable of the paramyxovirus structural proteins with only 22–40 percent amino acid homology being observed between each genus. The P proteins vary in size from 241 to 709 amino acids and are essential components of the viral polymerase complex.

P proteins are believed to serve as scaffolding proteins by binding both the nucleocapsid and the polymerase (L) proteins. In addition, P proteins act as chaperones for the N protein during nucleocapsid assembly. The active form of P is a tetramer and binding sites for P–P, P–L, P–N, and P–nucleocapsid interactions have been mapped for members of the respiroviruses and morbilliviruses. With the exception of the P–N-binding site, all are located in the unique carboxyl terminal domain. None of the proteins translated from edited mRNAs or alternative reading frames possess these sites. However, the binding site for the soluble N lies within the amino terminus of P and is shared with the V and W proteins (Curran et al. 1995). While information about the P proteins of the *Pneumovirinae* is not as detailed, the available data indicate that the functional domains are similar to those of the *Paramyxovirinae* (Hengst and Kiefer 2000).

The amino terminal domain of the P proteins (and the V proteins) of respiroviruses, morbilliviruses, and henipaviruses is 231–403 amino acids in length, acidic in nature and contains most of the serine and threonine phosphorylation sites. The amino terminal domain of the P proteins of the rubulaviruses and avulaviruses are smaller (134–164 amino acids) and basic in nature. Based on some limited sequence similarity, it has been speculated that the amino terminus of the P and V proteins of rubulaviruses share characteristics with the C proteins found in the other genera of the subfamily *Paramyxovirinae*. In this context, it is interesting that the rubulaviruses are the only genus in the subfamily that does not express a C protein.

V protein and other editing products

Most members of the subfamily *Paramxyovirinae* edit their *P* gene mRNA cotranscriptionally to access additional reading frames. The only exception is human parainfluenzavirus type 1, which has nine stop codons in the V reading frame (Rochat et al. 1992). V proteins are fusion proteins containing the terminal domain of P and a relatively short, conserved cysteine-rich C terminus. As for the P proteins, the amino terminus of the V protein of the rubulaviruses is basic, while the other genera express V proteins with acidic amino termini. The V proteins of the rubulaviruses also differ from those of the other genera by their localization in the nucleus of infected cells, the presence of RNA-binding domains, and the incorporation into virions (Thomas et al. 1988; Takeuchi et al. 1990). V proteins of the other genera are nonstructural proteins and localized in the cytoplasm of infected cells. The seven conserved cysteines in the unique carboxyl terminus of V proteins form zinc-binding domains.

The V proteins of rubulaviruses and morbilliviruses have been shown to interfere with the innate immune system by inhibiting interferon signaling (He et al. 2002; Rodriguez et al. 2002; Palosaari et al. 2003). The inhibition involves sequestering and/or degrading either STAT1 or STAT2 (Parisien et al. 2001). V proteins have been shown to bind a host-cell protein, damage-specific DNA-binding protein (DDB1) (Lin et al. 1998). V proteins inhibit genome replication in a dose-dependent fashion (Curran et al. 1991). Recombinant viruses defective in V expression have been generated for several species, demonstrating that V is dispensable for replication in cell culture. However, all of these viruses are attenuated in animal models, indicating that V proteins are virulence factors, probably due to their role as interferon antagonists (Kato et al. 1997; Schneider et al. 1997; Durbin et al. 1999).

The editing process is not limited to the addition of one G (or two in the rubulaviruses). The number of inserted Gs and relative abundance of edited transcripts vary between viruses. In several viruses, additional proteins have been detected, although their functions have not been determined. The insertion of two nucleotides opens the third reading frame in all genera, except rubulaviruses. These proteins include the W protein of Sendai virus and the D proteins of human parainfluenzavirus 3 and bovine parainfluenzavirus 3. In the rubulaviruses, addition of two Gs accesses the P ORF, but addition of one G leads to the production of the I protein.

C proteins

An overlapping ORF that encodes one or more short (156–215 amino acids), basic proteins can be found near the 5′ end of the P mRNA of the respiroviruses, morbilliviruses, and henipaviruses. The respiroviruses express up to four carboxyl coterminal proteins from different start sites in this ORF (C′, C, Y1, and Y2) (Curran and Kolakofsky 1989), while the other two genera express only a single C protein. Since the entire ORF is located upstream of the editing site, the C proteins are expressed from both edited and unedited transcripts of the *P* gene. Translation of some of the C related proteins of the respiroviruses start at non-AUG codons (Curran and Kolakofsky 1989). Most of these proteins are nonstructural, although small amounts of the C

protein of Sendai virus are found in virions (Yamada et al. 1990).

Several C proteins have been shown to interfere with the interferon response in a manner very similar to that described for V proteins (Gotoh et al. 1999; Shaffer et al. 2003). This function appears to be redundant in at least some viruses that express both C and V proteins. The C proteins of Sendai virus and measles virus have been shown to inhibit replication and transcription (Reutter et al. 2001; Curran et al. 1992), and the C of Sendai may have an additional role in virus assembly (Hasan et al. 2000). Recombinant viruses defective in C expression have been generated for several species, demonstrating that C is dispensable in cell culture (Baron and Barrett 2000; Radecke and Billeter 1996). However, many of these C minus viruses demonstrated altered growth characteristics and attenuation in vitro, and all of them were attenuated in animal models, indicating that C proteins are virulence factors (Valsamakis et al. 1998).

Matrix protein

As noted earlier, the matrix (M) proteins are the most likely candidates for interaction with lipids, the cytoplasmic tails of the glycoproteins (Sanderson et al. 1993) and the newly formed nucleocapsids (Stricker et al. 1994; Yoshida et al. 1986) in preparation for budding (Peeples 1991). The M proteins vary between 245 and 375 amino acid residues in length and are nonglycosylated proteins of an amphipathic nature. They contain both hydrophobic amino acids and basic amino acids. The latter lead to a net positive charge of +14 to +17 at neutral pH (Bellini et al. 1986; Sheshberadaran and Lamb 1990). However, despite the hydrophobic amino acids, M proteins do not contain transmembrane domains. Thus, it is believed that these proteins interact with the inner surfaces of the virion lipid envelope and plasma membrane. The M protein may be involved in the cessation of replication, orientation of particle release from the apical membrane, and interaction with the microtubule network (Tashiro et al. 1993, 1996).

Fusion protein

The F protein promotes fusion between the viral envelope and the plasma membrane of the host cell, as well as fusion between an infected cell and surrounding uninfected cells. These fusion events take place at neutral pH. F proteins are more highly conserved than the attachment proteins and form homotrimers. They are type I integral membrane glycoproteins, which have carboxyl termini extensions into the cytoplasm, while the amino terminus extends into the extracellular milieu. In all paramyxoviruses, F is synthesized as an inactive precursor, F_0. This precursor is proteolytically cleaved into two fragments, F_1 and F_2, which are linked by disulfide bonds and constitute the active form of the molecule. They contain a signal sequence at the amino terminus that is cleaved when the molecule is delivered to the endoplasmic reticular membrane for completion of synthesis. F proteins further contain a hydrophobic domain (known as a stop transfer signal) at the C terminus of F_1 that anchors the protein in the membrane. A short cytoplasmic tail of between 20 and 40 amino acid residues in length extends into the cytoplasm (Figure 2). Although regions of extensive amino acid homology are not obvious among the genera, there is similarity in the number and location of cysteine residues suggesting similar folded structures (Morrison and Portner 1991).

Cleavage of F_0 by intracellular or secreted host endoproteases creates two disulfide-linked subunits, F_1 and F_2. The efficiency of cleavage affects the host range and tissue tropism of the virus, such that greater cleavage efficiency is generally associated with disseminated infections and increased virulence, especially in Newcastle disease virus (de Leeuw et al. 2003). The F protein cleavage sites contain either a single or multiple basic amino acids. Viruses that contain a multibasic sequence are cleaved in the trans-Golgi network by a protease with the sequence specificity of R–X–K/R–R. An endoprotease, furin, has been identified as one protease having such properties (Barr 1991; Hosaka et al. 1991; Ortmann et al. 1994). Cleavage sites containing a single basic residue are cleaved by proteases expressed at the cell surface. Several candidate proteases have been identified (Gotoh et al. 1992). The cleavage site of the henipaviruses is unique in having the only F_1 protein that begins with a leucine instead of a phenylalanine (Wang et al. 2001). Most members of the genus *Pneumovirus* have two cleavage sites, both of which are required for activation (van den Hoogen 2004).

The larger subunit, F_1, contains a hydrophobic fusion peptide at its amino terminus (Figure 2). The fusion peptide, which is highly conserved among the *Paramyxovirinae*, mediates the fusion of the two membranes. There is less conservation in the fusion peptide within the members of the subfamily *Pneumovirinae*, and very little conservation exists between the fusion peptides of members of the two paramyxovirus subfamilies.

F_1 proteins of the *Paramyxovirinae* contain two heptad repeats (HR) (McGinnes et al. 2001). These are three to four repeats of seven amino acids, with hydrophobic amino acids in positions a and d. It is thought that engagement of the viral attachment protein triggers conformational changes in F that promote fusion (Dutch et al. 2001). The six HR in the F homotrimer form a six-helix bundle that represents the most stable form of the molecule and is required for fusion. HR A occurs adjacent to the fusion peptide and may be involved in the conformational alteration of this peptide that enhances fusion (Chambers et al. 1990). HR B is located adjacent to the transmembrane region. Peptides corresponding to HRs can inhibit fusion (Yao and

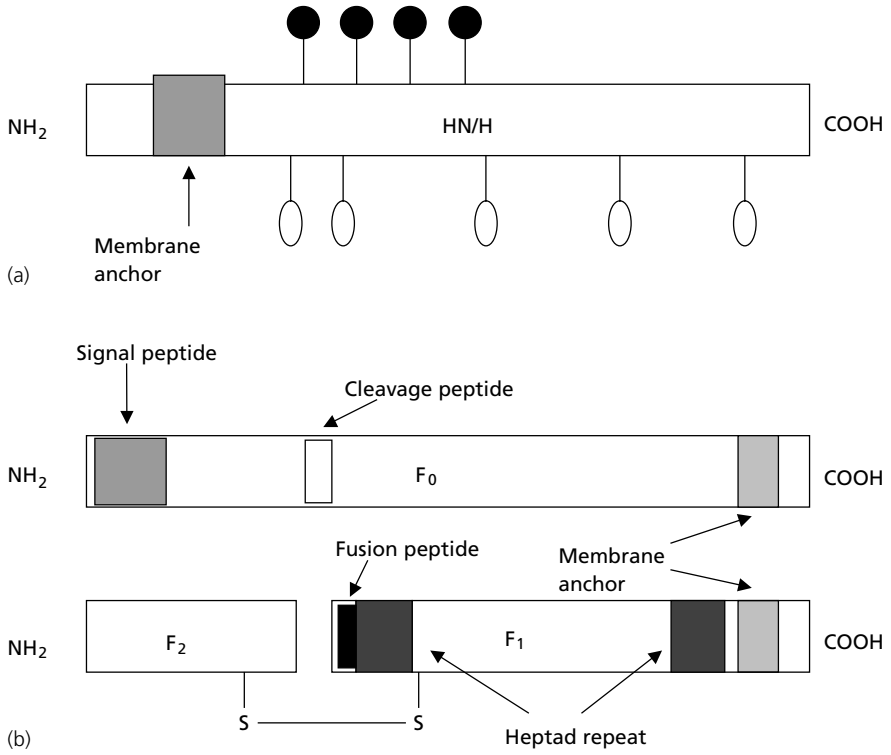

Figure 2 *Schematic diagrams depicting the most salient features of the attachment protein and fusion protein of the family* Paramyxoviridae. **(a)** *Figure shows an idealized HN or H attachment type II glycoprotein. The stop transfer or membrane anchor sequences are shown near the amino terminus of the molecule. The lollipop structures in black along the top of the diagram display the clustering of* N*-linked glycosylation sites observed in the* H *genes of many morbilliviruses, and the open structures display the more general distribution observed for the HN proteins. The G proteins (not shown) share the same orientation in membrane, contain both* N*-linked and* O*-linked glycosylation sites, and are about one-half the size of either HN or H.* **(b)** *The fusion (F) protein is a type I glycoprotein. The uncleaved form of F, F_0, is shown with a signal peptide at the NH2 terminus, which permits entry into the Golgi endoplasmic reticular lumen for membrane-associated protein synthesis. The cleavage peptide, made up of one or more basic residues, is indicated by the open box. Finally, the membrane anchor sequence at the COOH terminus is depicted. Also shown is the cleaved form of F_0 composed of F_1 and F_2 peptides. Note creation of a new NH_2 terminus on F_1 containing the fusion peptide. Regions of F1 containing heptad repeats for the* Paramyxovirinae *subfamily are also clearly labeled. The F protein contains* N*-linked sugar residues primarily on the F_2 molecule, but often on the F_1 as well. The F_1 and F_2 subunits are covalently linked via a single disulfide bond. (Figure courtesy of K. Sleeman.)*

Compans 1996; Young et al. 1997). The F proteins of paramyxoviruses share important structural features with the fusion proteins of viruses from other families including human immunodeficiency virus, Ebola virus, and influenza A virus. The common features include the structure of the core trimer, proteolytic cleavage requirement, and the position and composition of the HRs (Baker et al. 1999; Lamb et al. 1999).

F proteins of most genera are glycosylated on the F_1 and F_2 subunits except for the morbilliviruses and henipaviruses, in which only the F_2 subunit is glycosylated. Although the attachment proteins are the major targets of neutralizing antibodies, antibodies raised against F proteins are also able to neutralize infections.

Attachment protein

The attachment proteins of the *Paramyxovirinae* are type II integral membrane proteins. Such proteins have their amino termini extending into the cytoplasm from the inner surface of the plasma membrane and the carboxyl termini extending from the outer surface of the plasma membrane into the extracellular milieu (Figure 2). The attachment proteins of the morbilliviruses are referred to as H because they possess hemagglutination activity. The attachment proteins of respiroviruses, rubulaviruses, and avulaviruses have hemagglutination and neuraminidase activities and are abbreviated as HN. Since the attachment proteins of the henipaviruses and the *Pneumovirinae* do not possess hemagglutination nor neuraminidase activities, these proteins are referred to as G. The attachment proteins of the two subfamilies share no sequence homologies and therefore are treated separately in the following paragraphs.

There is considerable sequence homology between the H proteins of morbilliviruses and the HN proteins of the respiroviruses, rubulaviruses, and avulaviruses, while the G proteins of the henipaviruses are quite

different. The predicted amino acid sequences of HN proteins range in size from 565 to 582 amino acids, while the H proteins of the morbilliviruses and the G proteins of henipaviruses are larger having 602–617 amino acids. The HN protein of NDV is expressed as an inactive precursor, HN0, which is activated by removal of a carboxyl terminal fragment (Nagai et al. 1989). The HN/H/G proteins are glycosylated with *N*-linked oligosaccharides only, there are between three and eight potential sites per molecule. The general structure of the attachment proteins consists of a cytoplasmic domain, a membrane-spanning region, a stalk region and a globular head. The crystal structure of the NDV HN globular head has been determined (Crennell et al. 2000). Based on these data and extensive computer modeling, the globular head of the attachment proteins of the *Paramyxovirinae* is a propeller-shaped superbarrel of six cyclically arranged beta-sheets, and these proteins are believed to be disulfide-linked homodimers, two of which form noncovalently linked tetramers (Langedijk et al. 1997; Malvoisin and Wild 1993).

The attachment protein promotes fusion, as the ability of the F protein to fuse membranes depends on the presence of the homologous HN/H/G. The exception to this is the *Rubulavirus*, simian virus 5, which does not require the HN protein for fusion. It is believed that HN/H/G positions the membranes for access by the fusion peptide and/or causes a conformational change in F that allows fusion to occur. The fusion-helper function of HN/H/G only occurs with homologous F proteins or those of closely related viruses within the same genus (Bossart et al. 2002).

The HN glycoproteins of the paramyxoviruses and rubulaviruses employ sialic acid-containing cell surface molecules as receptors. The membrane distal globular head region contains the sialic acid-binding site. The HN proteins of respiroviruses proteins contain a conserved amino acid sequence (NRKSKS), similar to the sialic acid-binding site of influenza virus neuraminidase (Morrison and Portner 1991). The neuraminidase activity cleaves sialic acid residues, presumably to prevent budding virions from self-aggregation. Two cellular receptors have been identified for measles virus, CD46, a complement regulatory protein, and human SLAM (Dorig et al. 1993; Naniche et al. 1993; Tatsuo et al. 2000). The canine and bovine homologues of human SLAM serve as receptors for the morbilliviruses, canine distemper virus and rinderpest virus (Tatsuo et al. 2001).

The HN/H is also responsible for the ability of the viruses to bind erythrocytes. Whether there are two separate sites on HN proteins for hemagglutination and neuraminidase activity, or only one, remains unclear. The attachment proteins of the *Paramyxovirinae* are usually highly antigenic and are a major target for neutralizing antibodies.

The G proteins of the subfamily *Pneumovirinae* have little in common with the attachment proteins of the *Paramyxovirinae*, apart from their type II glycoprotein configuration and attachment property. G proteins are about half the size of HN and H proteins, the putative ORF of the G protein of human metapneumovirus is only 263 amino acids long (van den Hoogen 2004). They lack neuraminidase activity, and, with the exception of pneumonia virus of mice, also lack hemagglutination activity. There is little sequence homology even within the subfamily. G proteins probably exist as noncovalently linked trimers or tetramers (Wertz et al. 1989; Collins and Mottet 1992). The major distinguishing feature of the G proteins of the pneumoviruses is the abundance of *O*-linked sugar residues. *O*-linked glycosylation occurs at serine or threonine residues, which comprise 30 percent of the amino acid residues on the G protein of respiratory syncytial virus (Wertz et al. 1989; Collins and Mottet 1992). In addition, there are three to seven potential sites for *N*-linked glycosylation. *N*-linked glycosylation seems to occur co-translationally and is a requirement for the proper folding of the G proteins, as with the attachment proteins of the *Paramyxovirinae*. *O*-linked oligosaccharides are added after the folding is completed. The high carbohydrate content explains the difference between the predicted and apparent molecular weight of the G protein of respiratory syncytial virus (32.6 vs 90 kDa) (Wertz et al. 1985). While it is known that human respiratory syncytial virus attaches to glycosaminoglycans containing heparin sulfate, no specific receptors for this virus or other members of the subfamily have been identified.

Large (polymerase) protein

The gene closest to the 5′ terminus of the genome and the least abundant protein is the viral RNA-dependent RNA polymerase or large (L) protein. The protein accounts for 40–50 percent of the coding capacity of the viral genome. The large size of the protein (2 000–2 300 amino acid) reflects the many enzymatic and binding functions ascribed to this protein. The L proteins of the metapneumoviruses are the smallest, with only 2 004 amino acids for avian paramyxovirus (van den Hoogen 2004). The L protein is assumed to carry out all the enzymatic activities of the polymerase complex, namely initiation, elongation, and termination of both mRNA transcription and genome replication. mRNA transcription includes capping and methylation of the 5′ end of messages, as well as polyadenylation. The templates for poly(A) tails are the short poly(U) sequences that are part of the transcription termination signals of the genes. It is assumed that the polymerase moves back and forth over these sequences to synthesize poly(A) tails of more than 100 nucleotides. This process has been called ‘stuttering.’ A similar slippage effect is the basis for the

'editing' of the P mRNAs of the *Paramyxovirinae*. Whether L is involved in phosphorylation of other proteins remains uncertain.

It has recently been shown that the L proteins of respiroviruses form homo oligomers (Smallwood and Moyer 2004). Since P proteins form homo tetramers (Tarbouriech et al. 2000) and the ratio of L to P in the polymerase complex has been shown to be 1:4, the minimal polymerase complex would be L2P8; however, the exact composition is unknown. Since L proteins also interact with C proteins (Horikami et al. 1997; Sweetman et al. 2001; Smallwood and Moyer 2004), they must contain L–L-, L–P-, and L–C-binding sites, several of which have been mapped for morbilliviruses, respiroviruses, and rubulaviruses.

A comparison of the amino acid sequences of the L proteins of several members of the order *Mononegavirales* lead to the identification of six domains, which are characterized by a higher level of similarity (Poch et al. 1990). Within these domains lie shorter regions of even higher conservation that are assumed to be important for polymerase function. Several putative sites for template binding, ATP binding, and nucleotide binding have been identified. A highly conserved GDN motif in domain III may be the catalytic site for phosphodiester bond formation and be analogous to the GDD catalytic site in poliovirus. Interestingly, the amino acids flanking this motif are glutamine (QGDNQ) in all members of the family except in L proteins of the henipaviruses, which have a QGDNE motif (Harcourt et al. 2001).

L proteins are believed to function only in combination with homologous N and P proteins and on templates with homologous termini, although a few exceptions among closely related members of the same genus have been noted (Curran and Kolakofsky 1991). Therefore, binding sites and promoters have co-evolved. Data derived from experimental respiratory syncytial virus and bovine parainfluenzavirus 3 vaccine candidates demonstrate that mutations in L can play a role in viral attenuation (Crowe et al. 1996; Juhasz et al. 1997).

Small hydrophobic proteins

Simian virus 5 and mumps virus (genus *Rubulavirus*), avian paramyxovirus 6 (genus *Avulavirus*), and all members of the subfamily *Pneumovirinae* have genes encoding small hydrophobic proteins (SH). These proteins have little in common beyond the fact that they are integral membrane proteins and they share no sequence homologies. They vary in length from 44 to 183 amino acids. Some are type II membrane proteins (Bukreyev et al. 1997), while others are type I proteins (Takeuchi et al. 1996). The SH proteins of the metapneumoviruses have two potential transmembrane regions (van den Hoogen 2004). The SH proteins of simian virus 5 and human respiratory syncytial virus are structural proteins; however, this has not been proven for some of the other viruses. Spontaneous deletions of the gene or expression of defective SH proteins have been described for human respiratory syncytial virus and mumps virus strains, and recombinant viruses with deletions of the *SH* gene grow well in cell culture (Takeuchi et al. 1996). However, a recombinant human respiratory syncytial virus with a deletion of the *SH* gene was attenuated in chimpanzees (Bukreyev et al. 1997). The SH protein of simian virus 5 appears to be involved in the suppression of apoptosis (He et al. 2001).

NS1 and NS2 proteins

The members of the genus *Pneumovirus* encode two nonstructural proteins, NS1 and NS2. Their genes are located at the 3′ terminus of the genome, which leads to high levels of transcription. NS1 is 136–139 amino acids long, and NS2 is 124 amino acids in length. NS1 inhibits both transcription and replication in minigenome replication assays and NS2 had a similar, but much less pronounced effect (Atreya et al. 1998). Recombinant viruses with deletions of one or both genes demonstrate that these proteins are dispensable for growth in cell culture; however, the mutants are attenuated both in cell culture and in chimpanzees (Jin et al. 2000). NS1 and NS2 of bovine respiratory syncytial virus and human respiratory syncytial virus have been shown to protect the virus from the effects of interferon-α/β (Schlender et al. 2000; Bossert and Conzelmann 2002). Interestingly, the inhibition of interferon required expression of both proteins, indicating a cooperative action. It appears that the function of the NS proteins may be comparable to that of the C and V proteins of the *Paramyxovirinae*.

M2-1 and M2-2 proteins

All members of the subfamily *Pneumoviridae* have an *M2* gene, which expresses two proteins, M2-1 and M2-2. The M2-1 of human respiratory syncytial virus, also called the 22K protein, is 194 amino acids in length, and is a hydrophilic, phosphorylated, structural protein found associated with the nucleocapsids (Garcia et al. 1993). It acts as a processivity and antitermination factor in transcription (Collins et al. 1996; Hardy and Wertz 1998). The protein is required to transcribe longer genes completely and leads to an increase in read-through transcripts at intergenic junctions. M2-1 has no effect on replication. A C_3H_1 motif near the amino terminus, which may bind zinc, is conserved in all M2-1 proteins and is required for the function of the protein (Hardy and Wertz 2000). M2-1 binds RNA and the N protein (Cuesta et al. 2000). Deletion of the M2-1 ORF does not produce viable virus.

The M2-2 protein is translated from a reading frame that overlaps the end of the M2-1 ORF. The M2-2 protein of human respiratory syncytial virus is 90 amino acids in length and nonstructural. Deletion of the ORF produced a virus viable in cell culture, showing that the gene is dispensable; however, the mutant was attenuated in cell culture and in chimpanzees (Teng et al. 2000). The M2-2 minus mutant was further characterized by a shift from replication to transcription, with increased and continued mRNA production and decreased replication, suggesting that this protein is involved in regulating the balance of transcription and replication (Bermingham and Collins 1999).

INTRODUCTION

Acute measles is a well-defined clinical entity normally contracted by children and young adults. The causative agent, Measles virus (MeV), is an efficient pathogen, persisting in nature in populations large enough to support it, although it causes an acute infection only once in a lifetime of the individual. The virus is monotypic and antigenically stable, however, several genotypes can be distinguished some of which are inactive, while others are still active and are drifting on a genetic level worldwide. MeV is a highly successful virus, which has efficiently exploited its potential for spread. Although nonhuman primates are susceptible to infection, transmission from animals is not an important means of introducing the disease into a community. The virus may persist on rare occasions in single individuals for years, but these persistent infections are not associated with periodic shedding of infectious virus. A single attack of measles is sufficient to confer long-lasting, probably life-long immunity to re-infection. Consequently, in order to remain endemic in a given community, the virus must rely on the infection of unprotected susceptible individuals, mainly small infants with waning levels of maternal antibodies. The efficiency of this process is documented by the first known report of measles (in Egyptian hieroglyphics), which failed to recognize the infectious nature of the illness, and described it as a normal part of child growth and development.

In the prevaccine era, the maximum incidence of measles was seen in children aged 5–9 years in developed countries. Outbreaks and epidemics centered around elementary schools, while younger children acquired measles as secondary cases from their school-age siblings. By the age of 20, approximately 99 percent of subjects tested had been exposed to the virus. The introduction of the measles vaccine had a significant impact on the age incidence and percentage of measles cases in different age groups. In countries with an optimal vaccine implementation, measles infection has shifted to the teenage group, whereas in areas with inadequate vaccine programs children up to 4 years of age reveal a high primary measles attack rate (Bellini et al. 1994). In contrast, in developing countries, where measles has its greatest incidence in children under 2 years of age, the disease is a serious problem with a high mortality (up to 10 percent), with malnutrition being a precipitating factor for the severity of the disease. Therefore, the pattern of epidemiology observed differs markedly in different parts of the world, and a thorough understanding of this is essential to the development of successful vaccination programs.

CLASSIFICATION

Measles virus (MeV) is a member of the order *Mononegavirales* which includes the families *Rhabdo-*, *Filo-* and *Paramyxoviridae*. As a *Paramyxovirus*, MeV reveals structural and biochemical features associated

with this group (see General properties of the Paramyxoviruses). As it lacks a virion-associated neuraminidase activity and causes formation of intranuclear inclusion bodies, it has been grouped into a separate genus, *Morbillivirus* of which it is the type species. Other members of this genus include *Peste des petits ruminants virus* (PPRV), which infects sheep and goats, *Rinderpest virus* (RPV), which infects cattle, *Canine distemper virus* (CDV), which infects dogs, *Phocine distemper virus* (PDV), which infects seals and sea lions, dolphin morbillivirus (DMV), and porpoise morbillivirus (PMV) (see Paramyxoviruses of animals). All these viruses exhibit antigenic similarities, and produce similar diseases in their host species. Since MeV most closely resembles RPV, it has been suggested that the virus evolved in an environment in which cattle and humans lived in close proximity. Thus, measles is a relatively new disease of humans and a disease of civilization.

MORPHOLOGY, STRUCTURE, PHYSICOCHEMICAL, AND BIOLOGICAL PROPERTIES

MeV particles consist of a lipid envelope surrounding the viral RNP complex which is composed of genomic RNA associated with proteins (Figure 1a). Two transmembrane proteins (fusion (F) and hemagglutinin (H) proteins) project from the envelope surface. Both proteins extend through the virion envelope and appear on its inside surface. The H protein is anchored near its amino terminus (type II glycoprotein), and the F protein near its carboxy terminus (type I glycoprotein). One or both of the cytoplasmic domains functionally and probably physically interact with the matrix (M) protein (Cathomen et al. 1997a; Moll et al. 2001, 2002) which also links the envelope to the RNP core structure. The viral genomic RNA is fully encapsidated by nucleocapsid (N) protein and associated with the polymerase complex, consisting of the phosphoprotein (P) and the large (L) proteins, to form the RNP core structure that resists RNase degradation (Griffin and Bellini 1996). The virions are highly pleomorphic with an average size of 120 to >300 nm and both filamentous and irregular forms are known. The virion shown in an electron micrograph is bounded by a lipid envelope which bears a fringe of spike-like projections (peplomers) 5–8 nm long (Figure 2). The membrane below the spikes is 10–20 nm in thickness and the enclosed helical viral RNP core has a diameter of 17 nm and a regular pitch of 5 nm. The cargo space of the particles may vary from

3×10^5 to $>10^7$ nm^3 and could accommodate >30 genomes. In fact, packaging of multiple genomes within a single particle in vitro has been confirmed (Rager et al. 2002). Immediately below the membrane M proteins appear as a shell of electron dense material. The structure of the virion explains much of the early data concerning the stability of the virus. The integrity of the particle envelope is essential for infectivity which is inactivated by any compound which disrupts this structure, such as detergents or other lipid solvents including acetone or ether. Particles are acid labile and inactivated below pH 4.5, although they remain infectious between pH 5–9. MeV is thermolabile and has a half-life of 2 h at 37°C. Viability of the virus is maintained for 2 weeks at 4°C, but it is inactivated after 30 min at 56°C. Thermolability is probably due to an effect on the internal structure of the particle, since the hemagglutinin is relatively temperature resistant. The virus can be stored for

prolonged periods at −70°C and is amenable to freeze-drying. These properties have important consequences for the transport and storage of the vaccine.

Unlike other members of the morbilliviruses, MeV displays hemagglutination activity. This is easily demonstrated using monkey erythrocytes from rhesus, patas, and African green monkeys and baboons, but not from humans. MeV lacks detectable neuraminidase activity and does not attach to receptors containing sialic acid. Consequently, once attached to a red cell, MeV does not re-elute rapidly. H protein inserted into membranous structures is active in the hemagglutination test (HA). Virus particles separated by isopycnic centrifugation have a buoyant density of 1.23 g/cm^3, where HA activity is also detected. A large amount of hemagglutinating material is also found in the upper regions of the gradient (light hemagglutinin), which most likely represents H protein inserted into empty membranous cell fragments, or defective virus particles. Some lymphotropic MeV wild-type strains have very low hemagglutination activity which may be due to an additional *N*-linked glycosylation site within their H proteins or their low affinity for CD46, the MeV receptor expressed on monkey erythrocytes (see below). H is a major viral immunogen, and H-specific antibodies have hemagglutination-inhibiting (HI) and virus-neutralizing (NT) activities as they block the viral attachment to target cells. These antibodies do not prevent progressive viral cell-to-cell spread mediated by the F protein. The ability to lyze red blood cells once the virus has bound is mediated by the F protein. As with hemagglutination, this property is artificial, but hemolysis (HL) provides a convenient measure of F protein activity which is more sensitive to both pH and temperature than HA, and is optimal at 37°C and pH 7.4. The ability of the MeV to fuse at neutral pH accounts for the characteristic cytopathic effect (CPE) induced by these viruses, the formation of giant cells.

Genome structure, function, and replication

The 15 894 bases long viral genome is a nonsegmented RNA molecule of negative polarity that is entirely complexed with N proteins and the rigidity of this interaction is believed to account for the absence of genome recombination in the *Mononegavirales*. Each N protein covers six nucleotides, and this is thought to be the reason why only viral genomes whose number of nucleotides is a multimer of six are efficiently replicated by the viral polymerase. This constraint seems to be essential since in recombinant MeV genomes, hexameric genomic length ensuring accurate RNA encapsidation has been recently found to be actively restored (Rager et al. 2002). As long as the rule of six (Calain and Roux 1993) is maintained, MeV tolerates substantial variations in total genome length since recombinant genomes carrying foreign genes as diverse as reporter genes, heterologous envelope genes, or growth factors specificity domains displayed on the H protein can be rescued and stably propagated (Schneider et al. 2000). The standard genome is organized into six contiguous, nonoverlapping transcription units that are separated by (except for the M/F gene boundary) short noncoding regions containing signals for transcription termination, polyadenylation, and transcriptional re-initiation (Figure 1b, c) (Bellini et al. 1994). The genome is flanked by noncoding 3′ leader and 5′ trailer sequences containing specific encapsidation signals and the viral promoters used for viral transcription and/or replication of genomic and antigenomic RNAs (Horikami and Moyer 1995; Parks et al. 2001) (Figure 1c).

During transcription, the polymerase complex enters the genomic RNP at its 3′ end. After synthesis and termination of a short leader RNA, transcription is resumed at the gene start sequence 3′ of the N coding region and pauses at the gene stop sequence where, by a slippage mechanism, a poly(A) stretch is added. After liberation of the N mRNA, transcription of the downstream P mRNA is initiated. By the same stop–restart mechanisms, mRNAs for the other downstream genes are produced. As the polymerase tends to fall off the template at the intergenic boundaries, the probability of transcriptional re-initiation is lower than one, reflected by a decreasing transcriptional efficiency of downstream mRNAs (transcriptional gradient). The differential abundancies of the mRNAs directly translate into the relative amounts of proteins produced. Occasionally, the polymerase complex also ignores the intergenic stop/start signals giving rise to bi- or tricistronic, polyadenylated transcripts. Replication of the genome, or antigenome, respectively, tightly couples elongation and encapsidation. The switch from the transcription to the replication mode of the polymerase complex is thought to be dependent on the availability of N proteins for encapsidation.

From the *P* gene, two nonstructural proteins, C (20 kDa) and V (46 kDa) are expressed. While C protein is encoded within a separate reading frame (Bellini et al. 1985), V protein is translated from co-transcriptionally edited P mRNA. While its amino-terminal domain is identical to that of P, V protein has a unique cysteine-rich domain at the carboxy terminus (Wardrop and Briedis 1991). Editing (nontemplated addition of guanosine (G) ribonucleosides) is an intrinsic activiy of the MeV polymerase and occurs in about 50 percent of the P mRNAs. Additionally, an extremely low abundant protein, termed R, was reported to be expressed from the P mRNA and this required frame-shifting (Liston and Briedis 1995). As a pecularity of the morbilliviruses, an approximately 1 kb GC-rich region separates the M and the F ORFs. While several ORFs have been predicted for this region, these could only be accessed by translation from a rare bicistronic transcript

via ribosomal reinitiation. None of the putatively encoded proteins has yet been detected in infected cells.

MeV structural and nonstructural proteins

Since its first isolation, dissection of the MeV structure and replication strategy has been greatly aided by the development of tissue culture systems, the availability of monoclonal antibodies and, in particular, the availability of molecular biological approaches and techniques. The definition of MeV protein functions in more detail has long been limited by the lack of a system that allows a reverse genetic approach. As for other members of the *Mononegavirales*, plasmid-based systems to rescue infectious MeV in tissue culture have been developed and allow the introduction of stable alterations into the viral genome (Combredet et al. 2003; Radecke et al. 1995; Schneider et al. 1997; Takeda et al. 2000).

The viral RNP and nonstructural proteins

The N (nucleocapsid) protein (60 kDa; 525 amino acids (aa)), the most abundant of the MeV proteins, fully encapsidates the genomic RNA and this is the unique target for the viral polymerase to initiate transcription and replication. The protein is phosphorylated on serine and threonine residues (Gombart et al. 1995), and possibly tyrosine residues in persistent infections (Segev et al. 1995). It acts to condense the viral leader containing RNAs into a smaller, more stable, and more readily packaged form. This gives the nucleocapsid its helical form and 'herringbone' appearance in the electron micrograph (Figure 2). When expressed in the absence of viral RNA, N proteins, having undergone conformational maturation, aggregate into nuclear and cytoplasmic nucleocapsid-like structures. The N-terminal 398 amino acids are required for self-aggregation (Bankamp et al. 1996; Spehner et al. 1997) (Figure 3), while the C-terminal 125 residues are located outside the nucleocapsid. Since it contains a nuclear localization signal, N can be transported into the nucleus. The formation of high affinity protein complexes with the phosphorylated P (for which two noncontiguous domains (aa 4–188 and 304–373) are essential) prevents both nuclear translocation and self-aggregation of N proteins and encapsidation of cellular RNAs during replication of the viral genome (Bankamp et al. 1996; Huber et al. 1991). In addition, there is evidence for the formation of N/V complexes (Tober et al. 1998) (Figure 3). N protein also interacts with cellular proteins. A regulatory domain interacting with Hsp72 has been mapped within the C-terminal 24 amino acids of N, and this may be important for the enhancing effect of heat shock on MeV replication (Vasconcelos et al. 1998; Zhang et al. 2002). Moreover, direct interaction of N protein with IRF-3 and an IRF-3-associated virus-activated kinase may be involved in regulating interferon production during infection (Ten Oever et al. 2002) (Figure 3).

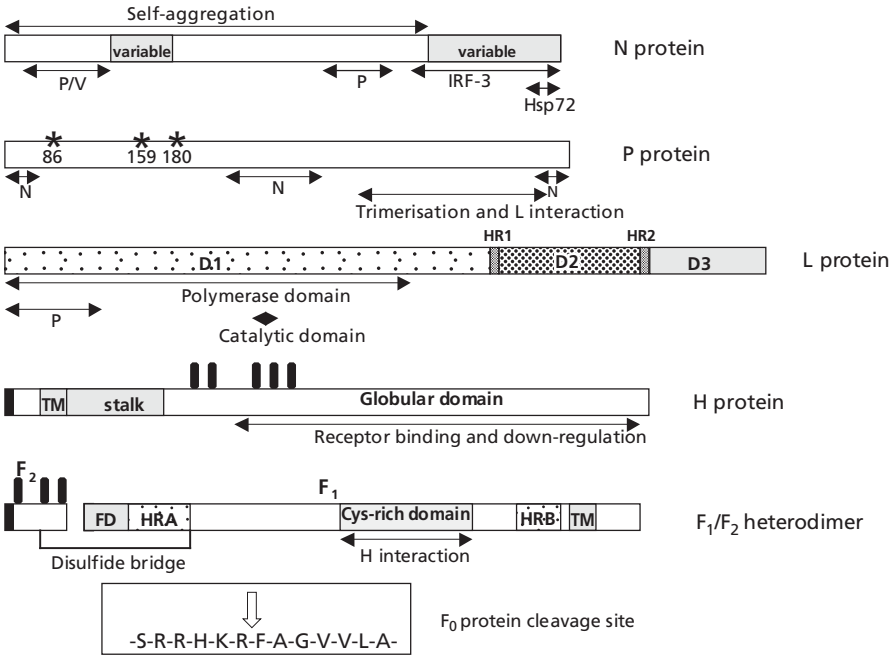

Figure 3 *Schematic representation of the major MeV structural proteins. Functional domains or those identified as essential for complex formation with MeV or cellular proteins are indicated by arrows. Phosphorylation sites within the P protein are indicated as asterisks, gylcosylation sites within the F and H proteins are marked. The sequence of the cleavage site within the F_0 protein precursor is indicated at the bottom. D1–D3, domains 1–3 within the L protein; FD, fusion domain; HRA and HRB, heptad repeat domain A and B; HR1, HR2, hinge region 1 and 2 separating domains within the L protein; Hsp72, heat shock protein 72; IRF-3, interferon response factor 3; TM, transmembrane domain.*

The P protein (72 kDa; 507 aa) is abundant in the infected cell, and only small amounts are packaged into virions. The protein is phosphorylated on serine residues 86, 151, and 180 most likely by the cellular casein kinase II (Das et al. 1995). As for the N protein, phosphorylation on tyrosine residues may occur in persistent infection (Ofir et al. 1996). Phosphorylation of P protein is essential for its function as polymerase cofactor. The protein oligomerizes into homotrimers via a predicted coiled-coil region in its carboxy-terminal domain (Curran et al. 1995; Harty and Palese 1995). Domains important for the interaction with the N protein reside in both the amino and carboxy terminus (Harty and Palese 1995), while a small central region (aa 204–321) was also found essential for the ability of P protein to induce N protein redistribution (Huber et al. 1991). Equally important for both transcription and replication, stable complexes between P and L have to be formed, and apparently L protein is stabilized by this interaction. Moreover, P is thought to act as *trans*-activator regulating L protein functions (Horikami and Moyer 1995) (Figure 3).

The diffusely distributed cytoplasmic V protein (46 kDa) is expressed from P mRNAs edited by insertion of a nontemplated G residue at position 751 after three genomically encoded Gs (Cattaneo et al. 1989a; Wardrop and Briedis 1991). As V protein shares the aminoterminal 231 amino acids with the P protein, it is also phosphorylated at the very same serine residues and is capable to form complexes via this domain with the N protein, but not to oligomerize or form complexes with the L protein (Liston et al. 1995; Tober et al. 1998). Its 68 amino-acid unique C-terminal domain is cysteine-rich and has zinc-binding properties (Cattaneo et al. 1989a; Liston and Briedis 1994).

The highly basic C protein (28 kDa) is also translated from the P mRNA by usage of a initiator codon 19 nucleotides downstream from that for P (Bellini et al. 1985). There is no evidence for its interaction with other MeV proteins, however both V and C proteins may interact with as yet undefined cellular proteins (Liston et al. 1995). The role of C and V proteins in MeV replication is uncertain. Recombinant MeV in which these reading frames were ablated can be rescued and efficiently amplified in standard cell cultures (Radecke and Billeter 1996; Schneider et al. 1997). These proteins may, however, regulate transcription and/or replication in specialized cell types and in MeV pathogenicity in vivo (Escoffier et al. 1999; Patterson et al. 2000; Tober et al. 1998; Valsamakis et al. 1998). As seen with C and/or V proteins of closely related viruses (Goodbourne et al. 2000), recent studies document that the nonstructural MeV proteins efficiently interfere with signaling via the IFN-α/β, and possibly also the IFN-γ, receptor (Palosaari et al. 2003; Shaffer et al. 2003; Takeuchi et al. 2003; Yokota et al. 2003).

The L protein (220 kDa; 2 183 aa) is expressed at low levels in infected cells and packaged into virions in only catalytic amounts. It is a multifunctional RNP-specific RNA polymerase producing mRNAs, replicative intermediates and progeny viral genomic RNAs (Bankamp et al. 2002). It also has multiple enzymatic activities (see also General properties of the Paramyxoviruses). Common to RNA polymerases, it contains a conserved duplicated GDDD motif flanked with hydrophobic residues (Bankamp et al. 1999; Blumberg et al. 1988). The polymerases of the *Mononegavirales* may function as multidomain proteins, and three well-conserved domains (D1, D2, and D3) which are linked by two variable hinges (H1 and H2) were defined by sequence alignments (Figure 3). Interestingly. D3 apparently enjoys a limited conformational independence from the other domains, since insertion of foreign reading frames into H1, but not H2, abolished replication of recombinant MeV (Duprex et al. 2002). Physical interaction with its co-factor, the P protein, requires the presence of the N-terminal 408 amino acids of the L protein.

The envelope proteins

The RNP core structure is surrounded by a lipid envelope with two glycoproteins on its external surface, the hemagglutinin (H) and the fusion (F) protein that are organized as functional complexes and appear as spikes in the EM. Both proteins are also expressed on the surface of infected cells. The H protein mediates viral attachment to receptors on the surface of target cells and also assists the F protein in causing fusion. Both proteins are protease-sensitive, as virions appear smooth under the EM following protease treatment. They can be isolated by gentle detergent lysis of the virion, although F tends to remain strongly associated with actin filaments. The spikes aggregate, presumably via the hydrophobic tails of both proteins which normally anchor them in the lipid bilayer.

The H protein, a type II glycoprotein, can be isolated as a tetrameric complex from the cell membrane. Analogous with the structure of the NDV HN protein, the ectodomain of the MeV H protein is thought to be organized into a membrane proximal stalk and a membrane distal globular head region composed of a six wing propeller structure (Crennell et al. 2000; Langendijk et al. 1997). It is folded and dimerized in the ER (Plemper et al. 2001a). Amongst the 13 strongly conserved cysteine residues within its ectodomain residues 287, 300, 381, 394, 494, 579, and 583 (all located within the globular domain) were found essential for oligomerization and folding (Hu and Norrby 1995). Moreover, cysteine 154 in the stalk region is essential for the formation of disulfide-linked dimers (Plemper et al. 2000; Santiago et al. 2002). Five potential glycosylation sites, four of which are used, are bunched within a region of 70 amino acids (aa 168–238), and glycosylation was found to be essential for proper folding, export from

the Golgi, antigenicity, and hemadsorption, probably by stabilizing the highly complex tertiary structure of the protein (Figure 3). Amino acids important for the differential interaction of MeV strains with their cellular MeV receptors, CD46 and CD150, respectively, which include aa 451, 481, 546, and 473–477, also map within the H protein ectodomain (Bartz et al. 1996, 1998; Hsu et al. 1998; Lecouturier et al. 1996; Patterson et al. 1999). In addition to its receptor binding function, H exerts a helper function in F-mediated membrane fusion probably by directing the fusion domain into the optimal distance to the target cell membrane and stabilizing the interaction (Nussbaum et al. 1995). The cytoplasmic domain of the H protein was found to be important for efficient cell surface transport of the molecule and harbors a basolateral sorting signal (Moll et al. 2001, 2002).

The F protein, a type I glycoprotein, is synthesized as inactive precursor (F_0; 60 kDa) from a mRNA which contains an up to 585-nt long 5′ noncoding GC-rich region that is thought to regulate its translational efficiency (Wild and Buckland 1995). The protein is glycosylated, oligomerizes, and is transported to the surface. The precursor is biologically activated by proteolytic cleavage at a conserved multibasic site (aa 108–112) by a subtilisin-like protease resident in the trans-Golgi to yield a disulfide-linked, biologically active F_1 (40kD)/F_2 (18 kDa) heterodimer (Bolt and Pedersen 1999; Sato et al. 1988). Glycosylation of the F_0 precursor is an essential prerequisite for cleavage and transport, and all potential *N*-glycosylation sites (aa 29, 61, and 67) reside within the F_2 subunit (Wild and Buckland 1995) (Figure 3). Because they most likely alter the conformation of this subunit, mutations of any of these sites affect cell surface transport, proteolytic cleavage, stability, and fusogenic activity of the F protein (Hu et al. 1995). The F_1 subunit reveals a topography typical for type I fusion proteins with an amino-terminal stretch of hydrophobic residues (the fusion domain), and two amphipatic α-helical domains, one of which is adjacent to the fusion domain, the other (containing a leucine-zipper motif) N-terminal of the transmembrane region (Bellini et al. 1994; Lambert et al. 1996). A central, cysteine-rich region (aa 337–381) is thought to mediate interaction with the H protein (Fournier et al. 1997; Wild and Buckland 1995) (Figure 3). Homo- and hetero-oligomerization of both glycoproteins takes place in the ER (Plemper et al. 2001b), and the strength of the F/H interaction and the fusogenic activity of the complex are also influenced by their cytoplasmic tails, both independent and dependent of their interaction with the M protein (Moll et al. 2001, 2002; Plemper et al. 2001a). Interestingly, the 33-aa long cytoplasmic tail of the F_1 subunit is frequently mutated in persistent infections (Billeter and Cattaneo 1994).

The M protein The M protein (37 kDa), translated from a mRNA with a 400 nt 3′ noncoding region (Bellini et al. 1986), is found associated with nucleocapsids and the inner layer of the plasma membrane in infected cells (Bellini et al. 1994; Griffin and Bellini 1996). Interaction of M protein with the cytoplasmic domains of one or both MeV glycoproteins has been documented in physical and functional terms (Naim et al. 2000; Plemper et al. 2001b). Thus, M protein was found to modulate the fusogenic activity of the F/H complex (Cathomen et al. 1997a,b) and interactions of M with the glycoprotein cytoplasmic tails allow M-glycoprotein co-segregation from to the apical surface in polarized cells (Naim et al. 2000). Recombinant MeVs carrying deletions of major parts of the *M* gene bud highly inefficiently thus supporting the initial suggestions that this protein might be essential in this process (Cathomen et al. 1997a). M protein may also negatively regulate MeV transcription when bound to RNPs (Suryanarayana et al. 1994). Mutations within the *M* reading frame are often found in persistent infections (Billeter and Cattaneo 1994).

THE REPLICATION CYCLE

Receptor interactions and entry

The expression of specific receptors available for the interaction with the MeV H protein on the surface of susceptible target cells is one of the most important determinants of viral tropism. During natural infection, MeV reveals a pronounced tropism for hematopoetic cells, but also enters into and replicates in a variety of cell types as it does in tissue culture. Thus, the receptor should be expressed on most human cells both in vivo and in vitro. This is the case for the first MeV receptor identified CD46 (membrane co-factor protein (MCP)), a member of the 'regulators of complement' (RCA) gene family (Doerig et al. 1993; Naniche et al. 1993) (Figure 4 and Table 1). CD46 is expressed on all nucleated cells, and is absent from human erythrocytes, which explains why these cannot be agglutinated by MeV H protein. By means of alternative splicing, several isoforms of CD46 are generated from a precursor mRNA in a tissue-specific manner and all of them support MeV uptake (Buchholz et al. 1996a; Johnstone et al. 1993; Manchester et al. 1994). The ectodomain of CD46 consists of four common membrane distal short consensus repeats (SCR 1–4), while the composition of the membrane proximal serine/threonine/proline (STP) segments and the intracellular carboxytermini (Cyt1 and Cyt 2) varies between the CD46 isoforms (Johnstone et al. 1993). CD46 normally binds complement components C3b and C4b via the SCR3 and 4 domains thereby preventing their deposition and formation of an attack complex on the cell surface (Liszewski et al. 1991). In contrast, an extended binding site for MeV H protein maps to SCR 1 and 2 (Casasnovas et al. 1999; Manchester et al. 1995). Glycosylation of these domains is apparently required (Maisner et al. 1994, 1996). The cytoplasmic tail of CD46 is dispensable for its MeV

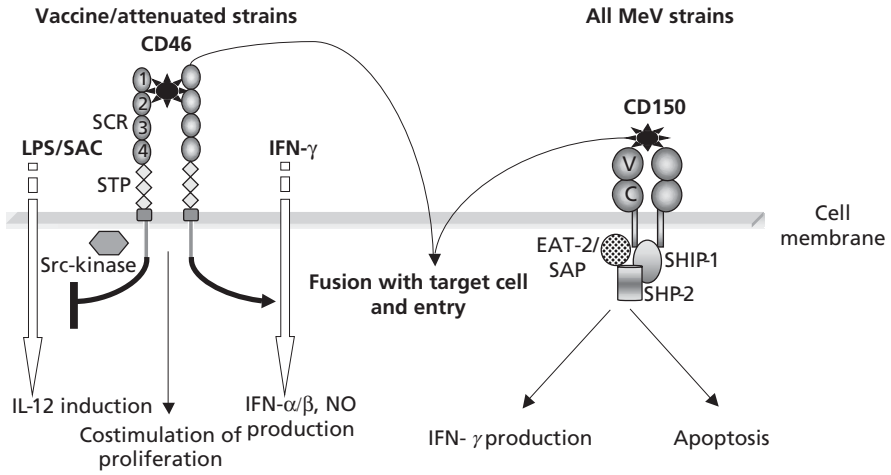

Figure 4 *Interaction of measles virus (MeV) with cell-surface receptors and consequences. MeV entry into target cells is supported by CD46 (mainly for attenuated strains) and CD150 (for all MeV strains). Both molecules have signaling properties. Tyrosine phosphorylation of the cytoplasmic domain of CD46 occurs in a Src family kinase-dependent manner, and CD46 ligation by MeV has been linked to enhancement of interferon γ (IFN-γ)-primed release of IFN-α/β and of NO production in CD46-transgenic murine monocytes. CD46-ligation can also suppress lipopolysaccharide (LPS) or* Staphylococcus aureus *Cowan strain I (SAC)-stimulated release of interleukin 12 (IL-12) from monocytes. Ligation of CD150 by specific antibodies triggers its activation, and the subsequent signaling is dependent of the presence of adaptor molecules such as SAP (for signaling lymphocyte activation molecule (SLAM)-associated protein) in T and natural killer (NK) cells and EWS/FLI1- associated transcript 2(EAT-2) in antigen-presenting cells. Triggering of CD150 is involved in recruitment and/or activity of phosphatases with protein (SHP-2; or Src-homology domain 2 (SH2)-domain-containing inositol phosphatase) or dual (SHIP-1; both protein and phospholipid) specificity, and in the induction of IFN-γ or cellular apoptosis. Established consequences of MeV-dependent regulation of signaling by CD150- or CD46-mediated signaling are indicated in plain text and those which have not yet been shown to be exerted by MeV in italics.*

receptor function (Varior-Krishnan et al. 1994), it has, however, signaling properties (Figure 4). MeV infection of cells of expression of H protein alone leads to CD46 down-regulation (Bartz et al. 1996; Krantic et al. 1995; Lecouturier et al. 1996; Schneider-Schaulies et al. 1996). Although CD46 was identified as MeV receptor by all criteria in human cells, transgenic expression of this molecule confered susceptibility to MeV infection in only some rodent cell lines and to intracerebral, but not peripheral infection in rodents indicating that as yet

Table 1 *Cellular surface molecules interacting with the MeV H protein*

	CD46	CD150	TLR2
Superfamily	Regulators of complement activity	Immunoglobulins	Pattern recognition receptor
Ectodomain	Four short consensus repeats and a variable number of serine–threonine–proline-rich repeats	One variable and one constant Ig-like domain	Repetitive leucine-rich repeats
Tissue distribution	All nucleated human cells	Activated T and B cells, thymocytes, differentiated monocyte/macrophages and dendritic cells	High on professional antigen-presenting cells
Cellular function	Protection from complement mediated lysis	Regulation of lymphocyte function	Activation of antigen-presenting cells
Endogenous ligand	C3b/C4b complement components	Self-ligand	None
MeV interaction			
Interacting MeV	Mostly vaccine and adapted strains	All MeV strains	MeV wild-type strains
Inhibition with specific antibodies	Yes	Yes	Yes
Regulation of host-cell functions	Yes	Yes	Yes
MeV uptake in transfected CHO cells	Yes	Yes	No

poorly defined determinants, including intracellular factors and possibly interferon, restrict MeV replication (Evlashev et al. 2001; Horvat et al. 1996; Mrkic et al. 1998; Naniche et al. 1993; Niewiesk et al. 1997b; Patterson et al. 2002; Vincent et al. 2002). It became, however, clear that the ability to use CD46 as entry receptor is confined to certain MeV strains, mainly vaccine strains and wild-type strains adapted to growth on Vero cells, while most lymphotropic wild-type strains and fresh isolates fail to interact with and to down-regulate CD46 (Bartz et al. 1998; Hsu et al. 1998). These and all other MeV strains tested as yet attach via their H proteins to CD150, a CD2-like molecule of the Ig superfamily (Erlenhoefer et al. 2001, 2002; Hsu et al. 2001; Minagawa et al. 2001; Ono et al., 2001a,b; Tatsuo et al. 2001) (Figure 4 and Table 1) with H proteins able to interact with both receptors revealing a higher kinetic binding rate for CD46 (Santiago et al. 2002). Amino acids essentially involved in the interaction of CD150 and the H protein have been mapped (Ohno et al. 2003; Vongpunsawad et al. 2004). CD150 is expressed by activated and memory T and B cells, and immature thymocytes, but not on freshly isolated monocytes and immature dendritic cells, but can, however, be induced on these cells upon stimulation (Aversa et al. 1997; Minagawa et al. 2001). For monocytes, this induction is mediated by interaction of the H protein of wild-type MeV strains with Toll-like receptor 2 (TLR2), which per se does not serve as entry receptor (Bieback et al. 2002) (Table 1). As for CD46, the most membrane distal portion of CD150, the V domain, is important for MeV binding (Ono et al. 2001b) (Figure 4), and the molecule is also down-regulated by MeV infection or H protein interaction (Erlenhoefer et al. 2001). Amino acids determining differential receptor usage of MeV H mainly include aa 481 and aa 546 and 451 (Bartz et al. 1998; Hsu et al. 1998; Lecouturier et al. 1996; Rima et al. 1997; Schneider et al. 2002). Similar to CD46, the cytoplasmic domain of CD150 has signaling properties (Latour et al. 2001; Mikhalap et al. 1999; Morra et al. 2001) (Figure 4). The ability of CD150 to confer susceptibility to MeV wild-type infection of lymphocytes, activated monocytes, and dendritic cells is clearly established (Hsu et al. 2001; Minagawa et al. 2001; Ohgimoto et al. 2001; Schneider et al. 2002; Tatsuo et al. 2001). Although CD150 can be induced on monocytes by TLR2 signaling, the question of how lymphotropic strains can enter into these natural target cells in vivo, the mode of MeV entry in CD150-negative cell types such as endothelial, epithelial (during acute measles), and brain cells (as prerequisite for central nervous system (CNS) persistence) is unknown (McQuaid and Cosby 2002). There is evidence for both low affinity interaction of these strains with CD46 and the existence of additional MeV receptors (Manchester et al. 2002; Takeuchi et al. 2002). For viral entry, interaction of the viral glycoproteins with cell surface molecules other than the known binding receptors may also be required. A role for both substance P receptors and moesin in this context has been suggested but not clarified (Dunster et al. 1994; Harrowe et al. 1992; Schneider-Schäulies et al. 1995b).

The presence of entry receptors is, however, not the sole determinant of tissue tropism and permissivity, as intracellular factors, particularly those associated with cellular maturation and activation, are also essential. Thus, the rodent adapted CAM strains of MeV (by as yet unknown receptors) and the Edmonston vaccine strain (and recombinant derivatives of this strain, by transgenic CD46) enter into and replicate well in neuronal cells of newborn and suckling, but not adult rodents (Duprex et al. 1999a, 2000; Finke and Liebert 1994; Lawrence et al. 1999, 2000; Liebert et al. 1990; Rall et al. 1997) and this is reflected by differential permissivity of maturing neuronal cultures in vitro (Duprex et al. 2000). MeV permissiveness in these systems is confined to the CNS, while intracellular factors restrict viral replication in most rodent cells in vivo and in vitro (see above). In human hematopoetic cells, viral replication is apparently dependent on cellular activation (Fugier-Vivier et al. 1997; Servet-Delprat et al. 2000b).

Intracellular replication, assembly, and budding

As all members of the *Mononegavirales*, MeV replicates exclusively in the cytoplasm of a permissive host cell. MeV transcription is initiated after specific attachment of the polymerase complex to the alleged promoter located within the 3′ end of the genome (Parks et al. 2001) (Figure 1b) and progresses to the 5′ end by transcribing monocistronic mRNAs. The tendency of the polymerase complex to disassociate from and reassociate with the template at the gene boundaries is apparently also controlled by host-cell factors, which is reflected by cell type-specific, differential slopes of the transcription gradient (Cattaneo et al. 1987; Griffin and Bellini 1996; Horikami and Moyer 1995; Schneider-Schaulies et al. 1989, 1995c). In the replication mode, the polymerase complex reads through the intergenic boundaries to yield a copy of the entire viral genome, the replicative intermediate. These full-length plus strands are about 100-fold less abundant than those of negative polarity. As replication requires a continuous supply of N protein, it is dependent on protein synthesis. In spite of the ability of the P protein to retain the N protein in the cytoplasm (Huber et al. 1991), intranuclear inclusion bodies consisting of N protein aggregates are typically seen late in infection. Cytoskeletal components may play a role during measles transcription/replication (Moyer and Horikami 1991). It is, however, likely that they are involved in transport of mature intracellular RNPs initially formed in the perinuclear area to the cell membrane (Duprex et al. 2000). They, or associated proteins, could

also be involved in the lateral movement of the MeV glycoproteins in the membrane required for patching and subsequent budding (Lydy et al. 1990). This may particularly refer to recruitment of the H protein into lipid rafts which may serve as platforms for MeV assembly. Upon co-expression with the F protein which has the intrinsic ability lo localize in rafts, the H glycoprotein is dragged into the rafts, and assembly of internal MeV proteins into these membrane domains requires the presence of the MeV genome. Synthesis, oligomerization, and maturation of the MeV glycoproteins has been referred to under MeV structural and nonstructural proteins. A sorting signal within their cytoplasmic domains mediates targeting of both MeV F and H proteins to the basolateral membrane in polarized cells, and interactions of M with the glycoprotein cytoplasmic tails allow M-glycoprotein co-segregation to the apical surface, suggesting a vectorial function of M to retarget the glycoproteins for apical virion release (Moll et al. 2001; Naim et al. 2000). The interaction of the cytoplasmic domains of the glycoprotein with M protein also negatively regulates the fusogenic activity of the complex (Cathomen et al. 1997a; Moll et al. 2001, 2002; Naim et al. 2000), and this may be important in viral spread by cell–cell fusion from the basolateral membrane of polarized epithelial cells and in brain tissue (Cathomen et al. 1997a; Ehrengruber et al. 2002; Moll et al. 2002; Naim et al. 2000). Functional inactivation of the M protein reading frame as often seen in persistent brain infections has thus been proposed to favor transneuronal spread in the absence of infectious virus production, which may occur even independent of the H protein (Duprex et al. 1999b, 2000; Ehrengruber et al. 2002; Lawrence et al. 2000; Patterson et al. 2001). Typically for morbilliviruses, the fusogenic activity of the F/H complex requires two conformational changes within the F protein, one of which is induced upon its proteolytic activation, the second after attachment of the H protein to its respective receptor(s) (Baker et al. 1999; Lamb 1993). The mechanism of budding is unclear, but the ability of M protein to aggregate in a crystalline array could confer upon it the capacity to distort the membrane into an outward-facing bulge, and ultimately to bud off the nucleocapsid inside a small vesicular structure. M is thought to act as a trigger in this process, and the absence of functional M protein has been suggested as a crucial element in persistence of MeV. The time taken for MeV replication in a permissive host cell is variable and becomes shorter as the virus adapts to growth in vitro. The growth of the Edmonston strain in Vero cells, is complete within 6–8 h, while for other strains, particularly fresh isolates, replication times of 7–15 days are not uncommon. Similarly, the alterations of host-cell macromolecule synthesis may vary between individual strains and cell types. Cell loss by fusion usually exceeds that caused by infection, and in some cell types, MeV infection induces apoptosis directly (Auwaerter et al. 1996; Grosjean et al. 1997; Okada et al. 2000).

Persistent infections

Persistent MeV infection can be easily established in tissue culture by several methods including passage of virus at high multiplicity with the generation of defective interfering particles, passage of infected cells in the presence of antibody, cultivating cells surviving lytic infection or infection with replication incompetent strains (Griffin and Bellini 1996). A variety of cell types can be persistently infected by one of these methods and factors favoring establishment of persistency include intrinsic or activation/differentiation-dependent regulation of viral RNA or protein synthesis (Schneider-Schaulies et al. 1992, 1993). Heat shock, IFN-inducible or RNA-binding proteins were found to be involved (Leopardi et al. 1993; Ogura et al. 1988) as were increased levels of cyclic AMP which may correlate with restrictions of MeV replication during neuronal differentiation in vitro and in vivo (Duprex et al. 2000; Schneider-Schaulies et al. 1989, 1993; Yoshikawa and Yamanouchi 1984). Moreover, signaling cascades triggered after interaction of MeV H protein with antibodies were found to further down-regulate MeV RNA synthesis in persistently infected neuronal cells (Schneider-Schaulies et al. 1992). There is, however, also evidence that the ability to establish persistent infection may depend on the MeV strain, which, in most cases, is produced in very limited amounts from persistently infected cells (Cattaneo et al. 1988b). In these viruses, mutations within the envelope protein genes lead to production of unstable or functionally impaired proteins (Billeter and Cattaneo 1994; Rima et al. 1995; Schneider-Schaulies et al. 1995c). Cellular protein synthesis is relatively unaffected by persistent MeV infection, although signaling cascades may be altered and specific cellular surface proteins down-regulated (Barrett et al. 1985; Meissner and Koschel 1995; Ofir et al. 1996; Schneider-Schaulies et al. 1992; Segev et al. 1994, 1995). Multinucleated giant cells due to cellular fusion are absent from these cultures, and this is consistent with stable down-regulation of the MeV H receptors from the cell surface (Bartz et al. 1996; Krantic et al. 1995; Schneider-Schaulies et al. 1996).

Measles genotypes

MeV is a serologically monotypic virus. Neutralizing antibody elicited to the Edmonston vaccine strain of measles virus is capable of neutralizing wild-type virus both in vitro and in vivo. With the advent of nucleic acid sequencing methods, regions of genetic variability along the measles genome have been defined (Rima et al. 1995) and exploited for use in what is currently known as ‘molecular epidemiology.’ The concept is very similar to that used to monitor polio control and eradication efforts. Maximum variability between strains of measles virus was observed within the last 450 nucleotides of the *N* gene, with as much as 12 percent nucleotide varia-

bility having been noted. The sequences of this region of the *N* gene and, when finer resolution is necessary, those encoding the entirety of the *H* gene, form the basis of differentiating lineages of wild-type and vaccine strains of MeV (Rota et al. 1996). In 1998, the World Health Organization (WHO) convened a meeting to establish a standard nomenclature for strain assignation. For molecular epidemiologic purposes, the genotype designations are considered the operational taxonomic unit, while related genotypes are grouped by clades (WHO 1998). WHO currently recognizes eight clades designated A, B, C, D, E, F, G, and H. Within these clades, there are 22 recognized genotypes. Genotypes are designated A, B1, B2, B3, C1, C2, D1, D2, D3, D4, D5, D6, D7, D8, D9, E, F, G1, G2, G3, H1, and H2. Some clades contain only a single genotype and, in such cases, the genotype designation is the same as the clade name. Other clades, such as clade D, contain multiple genotypes, and are designated by using the clade letter (in upper case) and genotype number (for example, D1, D2). Several of the genotypes, E, F, G1, D1, appear to be extinct or inactive, and representatives of these have not been isolated for at least 15 years. However, the sequences of the inactive genotypes are maintained in the set of WHO reference sequences for completeness (WHO 2001).

Genetic characterization of measles viruses has proven to be a powerful adjunct to the standard epidemiologic techniques that are used to study the transmission of measles. Genotyping data help suggest or confirm putative sources of virus or suggest a source when one is not obvious from epidemiological data. Genotypic data can also help to establish or to refute putative links between spread cases and outbreaks. Molecular surveillance is most beneficial when it is possible to observe the change in viral genotypes over time in a particular region because this information, when analyzed in conjunction with standard epidemiologic data, has helped to document the interruption of transmission of endemic measles. Thus, molecular characterization of MeVs has provided a valuable tool for measuring the effectiveness of measles control programs (Rota and Bellini 2003; Rota et al. 2004).

Vaccine strains differ from the wild-type isolates, and SSPE-derived sequences are much more similar to those seen in wild-type viruses. Based on these sequence similarities, it has been possible to identify wild-type MeVs having circulated in a given population as likely infectious agents found later in SSPE brain material. These findings resulted in two important conclusions: firstly, SSPE develops after infection with a wild-type MeV and not following vaccination, and secondly, circulating wildtype viruses, and not particular neurotropic strains, initially infect the CNS. So far, evidence indicates that measles is an antigenically stable virus and that the development of complications is not determined solely by the virus. Susceptibility of the host, age, and immune status at the time of infection, and possibly other factors, are almost certainly more significant than the invading virus. There is, however, no evidence to suggest that the currently used vaccines are not able to control MeV infection with viruses of differing genotypes.

CLINICAL AND PATHOLOGICAL ASPECTS

Acute measles

Measles, an inevitable disease of childhood prior to the vaccine era, has been studied in detail and clinical features are well documented. The course of acute measles is illustrated diagrammatically in Figure 5.
The virus is acquired via the upper respiratory tract, with tracheal and bronchial epithelial cells being important targets (Sakaguchi et al. 1986). Subsequently the virus reaches the draining lymph nodes from where, after a first round of amplification, it spreads to the rest of the reticuloendothelial system and respiratory tract through the blood (primary viremia). Giant cells containing inclusion bodies (Warthin–Finkeldy cells) are formed in lymphoid tissue and also on the epithelial surfaces of the trachea and bronchi. About 5 days after initial infection, the virus overflows from the compartments in which is has previously been replicating. The viremic spread of MeV to a variety of organs occurs almost completely cell-associated (by infected lymphocytes and monocytes (Esolen et al. 1993; Schneider-Schaulies et al. 1991) with little evidence of plasma viremia (Forthal et al. 1992). Consequently, MeV can be reisolated from the cellular, but usually not the cell-free fraction of blood samples before and at the time of the rash, and this is greatly assisted upon mitogen activation of the cells. MeV spreads to numerous organs (including viscera, bladder, kidney, and skin) where it replicates primarily in endothelial cells, epithelial cells and monocyte/macrophages. Giant cells are formed in all infected tissues, where lymphoid hyperplasia and inflammatory mononuclear cell infiltrates are characteristically seen. Infection of endothelial cells in small vessels is accompanied with vascular dilatation, increased permeability, and inflammation. After about a 10–14 days clinically latent incubation period, the patient enters the prodromal phase which lasts about 2–4 days. Infection-mediated destruction of cells of the thin epithelia of the respiratory tract and conjunctiva lead to the symptoms then observed. These consist of fever, malaise, sneezing, rhinitis, congestion, conjunctivitis, and cough, and a transitory rash can sometimes develop which has an urticarial or macular appearance, which disappears prior to the onset of the typical exanthema. At this time giant cells are present in the sputum, nasopharyngeal secretions, and urinary sediment cells (Katz 1995). Virus is present in blood and secretions, and the patient is

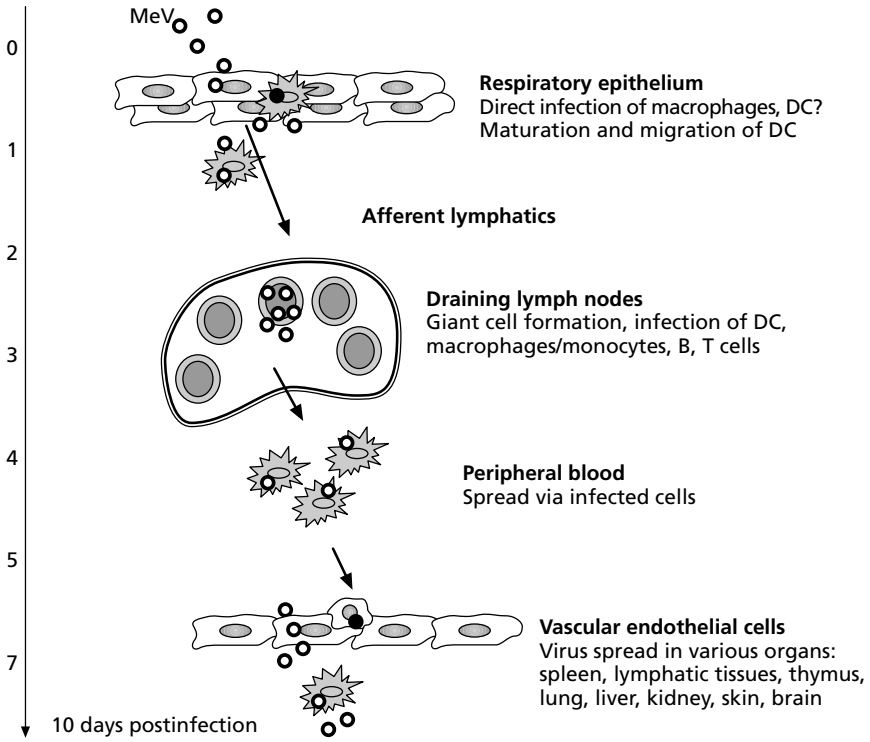

Figure 5 *Schematic representation of MeV (indicated by dots) uptake and dissemination.*

highly infectious. During this period Koplik's spots (raised spots with white centers, 1–3 mm, on an erythematous base), the pathognomonic enanthema of measles, appear on the buccal and lower labial mucosa opposite the lower molars. These begin to fade some 2–4 days after the onset of the prodromal phase as the rash develops.

The distinctive maculopapular rash appears about 14 days after exposure and starts behind the ears and on the forehead, then spreads within 3 days to involve the face, neck, trunk, and upper and lower extremities. The rash can become confluent, especially on the upper body and, once the entire body is covered, fades on the 3rd or 4th day. Histologically, the rash is characterized by vascular congestion, edema, epithelial necrosis, and round cell infiltrates. MeV antigen is absent from the spot and rash lesions, but is concentrated near blood vessels and in the endothelial cells of the dermal capillaries. The containment of infection in the skin is thought to be due to the development of cytotoxic T cells and to interferon production. As the rash results from accumulated damage to the vascular walls caused by this DTH reaction, it is often not observed in the immunosuppressed. Respiratory manifestations develop on the basis of diffuse mucosal inflammation in response to widespread MeV infection of epthelial cells and consequent inflammation of the lower respiratory tract. Gastrointestinal symptoms, mainly diarrhea, are common, while electrocardiographic abnormalities seen in about 30 percent of children with uncomplicated measles usually remain clinically insignificant. Although cerebrospinal fluid (CSF) pleocytosis and EEG changes are frequently seen in uncomplicated measles, neurologic disease in the course of, or after, measles is considered a complication rather than a pathognomonic finding. Once the exanthem has reached its height, the fever usually falls and the conjunctivitis as well as the respiratory symptomatology begins to subside. Antibody titers rise and virus shedding decreases from this point. Normally, the patient shows a rapid improvement. Continuation of clinical symptoms of the respiratory tract or fever suggests complications. On rare occasions, measles follows a hemorrhagic course, and this is characterized by high fever, seizures, delirium, respiratory distress, and hemorrhage into the skin and mucous membranes. In partially immune children, which include those with residual maternal antibodies or individuals who have received immune globulin as post exposure prophylaxis, measles can follow a special course, referred to as modified measles. Occasionally, this infection has also been seen in the course of live vaccine failure. It is usually characterized by a prolonged incubation period, mild prodrome, and sparse, discrete rash of short duration, and mild illness.

Atypical measles

This form of a measles was observed after incomplete measles vaccination prior to the exposure to natural MeV. The majority of reported cases received either

several doses of inactivated vaccine or a combination of inactivated vaccine followed by live-attenuated vaccine. The formalin-inactivated vaccine was administered in the United States from 1963 to 1967, and was withdrawn from the market soon after notification of the first cases of atypical measles (Clements and Cutts 1995). Therefore, this disease which was commonly associated with edema of the extremities and frequently with lobular or segmental pneumonia (accompanied by pleural effusion, which results in respiratory distress with dyspnea) is no longer seen. Its pathogenesis is still not fully understood. Hypotheses put forward included abnormally intense cellular immune responses, the inability of the inactivated vaccine to induce local respiratory tract immunity, and lack of production of F-specific antibodies allowing viral spread from cell to cell in the presence of neutralizing antibodies (Merz et al. 1980). As revealed more recently in macaques, the inactivated vaccine fails to induce affinity maturation of complement-fixing antibodies and the disease most likely results from a boosted anamnestic response and is mediated by immune-complex formation and eosinophilia in the presence of fusion-inhibiting antibodies (Polack et al. 1999, 2003).

Complications of measles infection

Complications of acute measles are relatively rare, and the majority results from opportunistic secondary infection of necrotic surfaces, such as those in the respiratory or gastrointestinal tract. Bacteria and other viruses can invade to cause pneumonia or other complications such as otitis media, bronchitis, or severe forms of diarrhea. The most severe complications caused directly by MeV are giant cell pneumonia and measles inclusion body encephalitis (MIBE), both of which occur in the immunocompromised patient, as well as postinfectious encephalitis (PIE) and subacute sclerosing panencephalitis (SSPE) in which no underlying susceptibility factor has been identified. Other unusual manifestations which may complicate acute measles are myocarditis, pericarditis, hepatitis, appendicitis, mesenteric lymphadenitis, and ileocolitis. If measles infection occurs during pregnancy spontaneous abortions or stillbirth may occur as well as an increased rate of low birth-weight infants. Congenital malformations have also been reported.

RESPIRATORY COMPLICATIONS

Symptomatic giant cell pneumonia is seen primarily in the immunocompromised due to unlimited and massive spread of virus to the lower respiratory tract (Breitfeld et al. 1973; Pullan et al. 1976). It is, however, mainly due to secondary bacterial and viral infections that most cases of severe pneumonia complicating measles and leading to chronic pulmonary diseases develop on the basis of the immunosuppression associated with measles (Gremillion and Crawford 1981; Katz 1995).

NEUROLOGICAL COMPLICATIONS

Postinfectious encephalitis (PIE) and measles inclusion body encephalitis

Transient EEG abnormalities as observed in some patients with acute measles suggests CNS involvement is not uncommon, although it is still a matter of controversy of whether and how MeV may reach this compartment. Acute postinfectious encephalitis (PIE) during the course of measles is a severe complication and is reported in approximately 0.1 percent of cases. In general, about 15 percent of cases are fatal, and 20–40 percent of those who recover are left with lasting neurological sequelae. Encephalitis usually develops when exanthem is still present within a period of 8 days after the onset of measles, but occasionally during the prodromal stage. PIE is characterized by resurgence of fever, headache, vomiting, seizures, cerebellar ataxia, and coma. In common with PIE induced by other viruses, this condition reveals perivascular cuffing, gliosis, and the appearance of fat-laden macrophages near the blood vessel walls and demyelination consistent with immunopathology (Gendelman et al. 1984). CSF findings in measles encephalitis consist usually of mild pleocytosis and absence of measles antibodies. Long-term sequelae include selective brain damage with retardation, recurrent convulsive seizures, hemi-, and paraplegia. Since there is little evidence for MeV RNA or antigen in the brain (Gendelman et al. 1984; Moench et al. 1988), PIE is most likely due to virus-induced autoimmunity to brain antigens (Johnson et al. 1984). In CSF specimens of PIE patients, myelin basic protein (MBP) was detected as a consequence of myelin breakdown and PIE patients and experimentally infected animals may exhibit a proliferative T-lymphocyte response to MBP (Johnson et al. 1984; Liebert et al. 1988). Since PIE is characterized by demyelinating lesions in association with blood vessels as in experimental allergic encephalitis, an MBP-specific lymphoproliferative response in measles infection is considered to be of pathogenetic importance. Mechanisms involved in triggering a T cell-mediated autoimmune response are unknown, and may include molecular mimicry or a deregulation of autoreactive cells occurring secondary to viral infections of lymphocytes.

As measles inclusion body encephalitis (MIBE) only develops in immunosuppressed patients, mainly in children with leukemia undergoing axial radiation therapy (Bitnun et al. 1999; Roos et al. 1981), it can be regarded as an opportunistic MeV CNS infection. In contrast to PIE, viral RNA and antigens are abundant in post mortem brain tissue (Baczko et al. 1988; Bitnun et al. 1999; Roos et al. 1981). The incubation period ranges from a few weeks to 6 months, and the patients often

present without a rash. The condition commences with convulsions, mainly myoclonic jerks, and is frequently confused with subacute sclerosing panencephalitis (SSPE). The seizures are often focal and localized to one site. Other findings include hemiplegia, coma, or stupor depending on the localization of the infectious disease process within the CNS. The disease progresses much faster than SSPE and death occurs within weeks or a few months. No or only low titers of MV-specific antibodies are detectable in the CSF.

Subacute sclerosing panencephalitis (SSPE)

SSPE, a fatal, slowly progressing degenerative CNS disease is seen in children and young adults usually 6–8 years after measles, although it can also occur up to 20–30 years after primary infection. Boys are more likely to develop SSPE, but the overall incidence is low (about 2–7 cases per 100 000 of acute measles). Half of the SSPE patients have contracted measles before the age of 2 years, and no unusual features of acute measles have ever been demonstrated. SSPE starts with generalized intellectual deterioration or psychological disturbance which may last for weeks to months and only be recognized as illness until more definite signs appear. These are neurological or motor dysfunctions, such as dyspraxia, generalized convulsions, aphasia, visual disturbances, or mild, repetitive simultaneous myoclonic jerks. The invasion of the retina by MeV leads, in 75 percent of cases, to a chorioretinitis of the macular area followed by blindness. The disease proceeds to progressive cerebral degeneration leading to coma and death within 1–3 years; more rapid forms are, however also known (Katz 1995).

Neuropathologically, a diffuse encephalitis affecting both the white and the gray matter is observed, characterized by perivascular cuffing, diffuse lymphocytic infiltration, and gliosis. Fibrous astrocytes, neurons, and oligodendroglial cells contain massive amounts of intranuclear inclusion bodies (Cowdry bodies), which contain MeV nucleocapsid structures, while giant cell formation or membrane changes consistent with virus maturation or release are not seen (Budka et al. 1982). The lesions lead to characteristic, pathognomonic EEG changes consisting of periodic high-amplitude slow wave complexes, which are synchronous with myoclonic jerks recurring at 3.5–20-s intervals and are remarkably stereotyped. They are bilateral, usually synchronous, symmetrical, consist of two or more delta waves with bi- or polyphasic appearance and may disappear as the disease progresses. Another pathognomonic finding is the state of humoral hyperimmunity against MeV in serum and CSF. The isotypes of MeV-specific antibodies found in CSF include IgG, IgA, and IgD, and in this compartment the immune response is of restricted heterogeneity (Doerries et al. 1988). For diagnostic purposes, determination of measles antibody in the CNS may be sufficient with, if necessary, demonstration of MeV-specific heterogeneity by isoelectric focusing in combination with an immunoblot technique.

OTHER CHRONIC DISEASES

Unlike its clear role in the etiology of the diseases outlined above, MeV has also been implicated in the pathogenesis of Paget's disease (Basle et al. 1986), chronic active hepatitis (Robertson et al. 1987), multiple sclerosis (Allen and Brankin 1993; Haase et al. 1981), and Morbus Crohn (Uhlmann et al. 2002). For each of these diseases an etiological link to measles or measles vaccination is controversial and for none has a definite role for MeV been identified (Birch et al. 1994; Duclos and Ward 1998; Moench et al. 1988).

PATHOGENESIS OF MEASLES AND PERSISTENT MeV CNS INFECTIONS

MeV can replicate in a variety of tissues, including cells of the immune system, and its interaction with the immune system is responsible for some of the key features of the disease. A DTH reaction is implicated in the production of the rash and the ability of the virus to cause a transient, generalized immunosuppression accounts to a major extent for complications associated with acute measles.

The study of MeV pathogenesis in animal models is almost exclusively confined to nonhuman primates which are permissive for intranasal MeV infection and develop disease which shares important features with that seen in humans (van Binnendijk et al. 1995). Attempts to induce measles-like disease in small animals by this route have largely failed (Liebert and Finke 1995). In rodents, MeV replication is impaired due to intracellular restriction as both rats and mice genetically engineered to express CD46, one of the MeV receptors, fail to replicate the virus after peripheral infection (Niewiesk et al. 1997b). Intracerebral infection of small rodents, both transgenic and nontransgenic, has, however, significantly contributed to the understanding of MeV CNS pathogenesis (Liebert and Finke 1995). For unknown reasons, cotton rats reveal a certain permissivity to intranasal MeV infection (Wyde et al. 1992), and, as with acute measles, experimental infection of these animals is accompanied by features compatible with immunosuppression.

Acute measles

MeV receptor interactions in pathogenesis

The usage of cellular receptors, which are discussed under The replication cycle, is an important aspect of MeV pathogenesis. Both CD46 and CD150 are down-regulated from the cell surface after contact with their respective interacting MeV H proteins and after infection (Erlenhoefer et al. 2001; Krantic et al. 1995; Schneider-

Schaulies et al. 1995a). For CD46, at least one consequence of MeV-induced down-regulation is known. Corroborating the 'natural' function of CD46 as a complement regulator, MeV-induced CD46 down-regulation enhances sensitivity to lysis by activated complement of lymphocytes in vitro (Schneider-Schaulies et al. 1996; Schnorr et al. 1995). CD46 can act as a signaling molecule, and ligation of this molecule phosphorylation of tyrosine residues within its cytoplasmic domain 2 occurs in a src family-dependent manner (Wang et al. 2000) (Figure 4). Coligation of CD3/CD46 by antibodies enhances T-cell proliferation and activation of signaling molecules, such as by $p120^{CBL}$, LAT, CrkL, Vav, Rac, and ERK indicating that CD46 can act as a co-stimulatory molecule (Astier et al. 2000; Zaffran et al. 2001). In CD46 transgenic murine macrophages, MeV-infection induced NO and type I IFN production in the presence of IFN-γ (Katayama et al. 2000) and CD46 ligation by MeV, CD46-specific antibodies or C3b/C4b complement components, interfered with stimulated IL-12 synthesis in monocyte cultures (Figure 4) (Karp et al. 1996). Moreover, the ability of CD46-specific antibodies to induce the generation of regulatory T cells in vitro upon CD3 co-ligation has been described (Kemper et al. 2003). Whether this also applies to CD46 ligation by MeV needs to be determined. Consequences of CD150 down-regulation or ligation by MeV remain speculative. Signaling events triggered after ligation of this molecule are complex and can lead to activation but also cellular apoptosis (Mikhalap et al. 1999). Coupling of CD150 to intracellular signaling pathways requires adaptor proteins, such as EAT-2 in antigen-presenting cells (Morra et al. 2001) or SAP in T and NK cells (Latour et al. 2001). In lymphocytes, CD150 ligation by antibodies recruits SHIP-1, a dual specific phosphatase, and thereby regulates recruitment of intracellular signaling molecules (Latour et al. 2001) (Figure 4). IFN-γ production from $CD4^+$ T cells can be enhanced upon CD150 ligation (Aversa et al. 1997), and thus it is tempting to speculate that downregulation of this molecule may play a role in impaired Th1 responses as seen in measles (Griffin 1995). Recent evidence, however, suggests that CD150 is more involved in regulating IL-4, rather than IFN-γ, release and thus, consequences of MeV interaction with this molecule remain speculative (Wang et al. 2004).

IMMUNE RESPONSES

MeV induces a marked immune activation as evidenced by spontaneous proliferation of PBMC, polyclonal activation of B cells, expression of activation markers on T cells, and increased plasma levels of cytokines and soluble surface proteins, such as CD4 and IL-2R (Griffin 1995). This activation is co-incident with a generalized immune suppression, and both may continue for many weeks after apparent recovery from measles.

Immune activation

Activation of $CD8^+$ T cells during measles is amply evidenced by proliferation of these cells and the appearance of MeV-specific HLA-restricted $CD8^+$ cytotoxic T lymphocytes in the blood at the time of the rash, some of which develop into CD8 memory cells (van Binnendijk et al. 1990). MeV antigens inducing $CD8^+$ cytotoxic T cells have not been completely identified, however, the F protein is one target for MHC class I-restricted T cells (van Binnendijk et al. 1989). A recent study suggests that the CD8 response plays an important role in the control and clearance of MeV infection (Permar et al. 2003a). $CD4^+$ T cells are also activated in response to MeV infection. Virion protein uptake to an endosomal compartment for subsequent MHC class II-dependent presentation can be triggered by the interaction of H protein with CD46 (Gerlier et al. 1994). $CD4^+$ T cells proliferate during the rash, and classical $CD4^+$ T cell responses such as MeV-antigen-stimulated cytokine production and MHC class II-restricted antigen-specific proliferation are stimulated (Griffin 1995). During the prodrome, plasma levels of IFN-γ, neopterin, and soluble IL-2R rise, followed by elevation of IL-2, soluble CD4, and CD8 at the time of the rash (Griffin et al. 1989, 1992). Subsequently, IL-4 becomes elevated, and this may persist for prolonged periods. This pattern of cytokine production is consistent with an early activation of $CD8^+$ and Th1 $CD4^+$ T cells followed by a predominant Th2 $CD4^+$ T-cell response during recovery (Figure 6). Whether or not Th1 responses are less efficiently generated after vaccination has not been entirely resolved (Gans et al. 1999; Griffin and Ward 1993; Schnorr et al. 2001).

Antibodies, which appear at the time of the rash, are initially of the IgM and then switch to IgG1 and IgG4

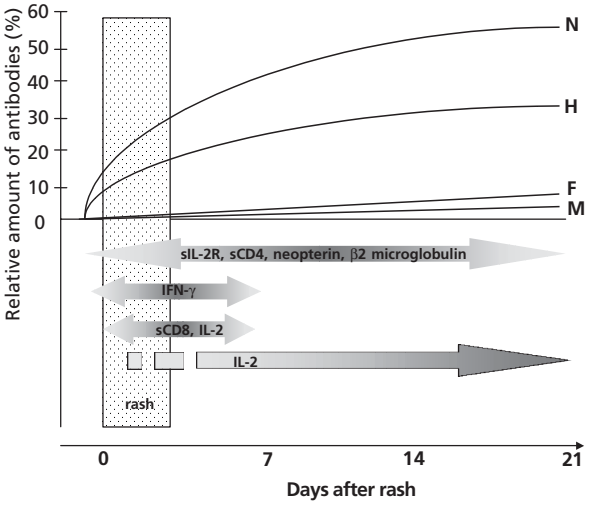

Figure 6 *Activation of immune responses during measles. Relative amounts of antibody produced to individual MeV proteins (upper part) and parameters (plasma levels of cytokines and soluble CD4, CD8, IL-2R, and β2 microglobulin, bottom part) in the course of acute measles.*

isotype (Griffin 1995). IgA, IgM, and IgG antibodies are found in secretions. Though antibodies are generated to most viral proteins, the most abundant and rapidly produced antibodies are N-specific (Figure 6). Antibodies to the H protein are neutralizing and inhibit agglutination of monkey erythrocytes by MeV by blocking the interaction of H protein with monkey CD46. Antigenicity of the H protein is variable, and up to six major, mainly conformational, epitopes were mapped by competitive binding of monoclonal antibodies (Carter et al. 1983). H-specific antibodies may also inhibit hemolysis, which is, however, a major property of F-specific antibodies. Up to seven linear epitopes within the F protein are recognized by polyclonal sera, and monoclonal F-specific antibodies can cross-react with cellular heat shock proteins (Sheshberadaran and Norrby 1984).

Early nonspecific and innate immunity

Unlike adaptive immunity, the role of early nonspecific and innate immunity in measles is poorly understood. NK-cell activity may be slightly reduced in measles (Griffin and Ward 1990). While production of type I IFN has been documented after vaccination, the production of this cytokine has not been unequivocally observed in patients with measles infections at the time of the rash (Shiozawa et al. 1988). As suggested by recent evidence, MeV vaccine and wild-type strains may also differ in their ability to induce type I IFN and to evade from IFN-mediated control in vitro in PBMC cultures (Naniche et al. 2000). The quality, magnitude, and duration of MeV-specific adaptive immunity is, however, likely to be governed to a major extent by its interaction with professional antigen-presenting cells such as tissue resident macrophages and DCs which reside at or close to its entry sites and fulfill a sentinel, but most likely also a Trojan horse function for MeV transport to the draining lymph nodes. In vitro, both immature and LPS- or CD40-matured DC are infectable with MeV, albeit virus production from pure DC and transmission of virus in DC/T cell co-cultures is very limited (Fugier-Vivier et al. 1997; Grosjean et al. 1997; Klagge et al., 2000; Schnorr et al. 1997b; Servet-Delprat et al. 2000b). There is evidence that wild-type MeV reveal a particular tropism for these cells, which is essentially determined by the interaction of the H protein with CD150 (Ohgimoto et al. 2001; Schnorr et al. 1997b). MeV infection triggers rapid maturation of immature DC as indicated by up-regulation of MHC class II and co-stimulatory molecules, and this again seems to occur more efficiently with certain wild-type strains (Dubois et al. 2001; Klagge et al. 2000; Servet-Delprat et al. 2000b). Cytokines induced in DC as well as in monocytes by MeV infection include IL-1-α/β, IL-1R antagonist, IL-6, TNF-α, type I IFN, and low amounts of IL-12p35 and IL-12p40 (Bieback et al. 2002; Klagge et al. 2000; Schnorr et al. 1997b; Servet-Delprat et al. 2000b), some of which trigger DC maturation or are directly involved in polarizing ensuing T-cell responses (Figure 7a). As outlined under The replication cycle, TLR2 signaling by wildtype MeV is involved in maturation of monocytes (Bieback et al. 2002). Signaling pathways triggered by its activation include the MAP kinases, the Akt kinase, and the NF-κB pathway, and ultimately result in production of proinflammatory cytokines, chemokines, as well as co-stimulatory molecules and CD150 (Aderem and Ulevitch 2000; Bieback et al. 2002). Activation of monocytes and DC is also induced by non-TLR2 agonistic attenuated MeV strains, and this may relate to the ability of intracellular MeV to activate NF-κB directly (Dhib-Jalbut et al. 1999; Hummel et al. 1998). Alternatively, induction of type I IFN does occur particularly with attenuated MeV strains, which, however, again, could be dependent on activation of a TLR, namely TLR3, which recognizes double-stranded RNA (Doyle et al. 2002). Interestingly, TLR3 was found to be up-regulated by laboratory, but not wild-type MeV strains as a consequence of IFN-induction (Tanabe et al. 2003).

MeV-induced immunosuppression

At the same time, when MeV-specific immunity is efficiently generated, a general suppression of responsiveness to other pathogens is established. This was recognized long before the virus was isolated and is the major reason for the constantly high morbidity and mortality rate associated worldwide with acute measles. Typically, patients reveal a marked susceptibility to opportunistic infections and lymphopenia affecting both B and T cells (Okada et al. 2000). The latter is not associated with a decrease in thymic output (Permar et al. 2003b) and may therefore result from lymphocyte depletion due to viral infection, apoptosis or aberrant homing of T cells (Addae et al. 1995; Auwaerter et al. 1996; Nanan et al. 1999; Okada et al., 2000). Immunosuppression, however, is observed up to weeks after the onset of the rash when the lymphocyte counts have returned to normal and MeV-infected cells are, if at all, present with only low frequency (Okada et al. 2001). Key features of MeV-induced immunosuppression are inhibition of DTH responses and a restricted ability of lymphocytes to proliferate in response to recall antigens, as well as polyclonal stimulation (Borrow and Oldstone 1995; Schneider-Schaulies et al. 2001) (Table 2). As only a few infected cells are usually detected, several hypotheses have been put forward to explain this finding which include the production of inhibitory factors by infected cells that have not yet been identified (Fujinami et al. 1998). Characteristics of MeV-induced immunosuppression are compatible with deregulation of APC viability and functions, which would be expected to be of significant impact on the induction, efficiency and quality of T-cell responses (Table 2). MeV infection causes maturation of immature DC, yet this may be incomplete, and

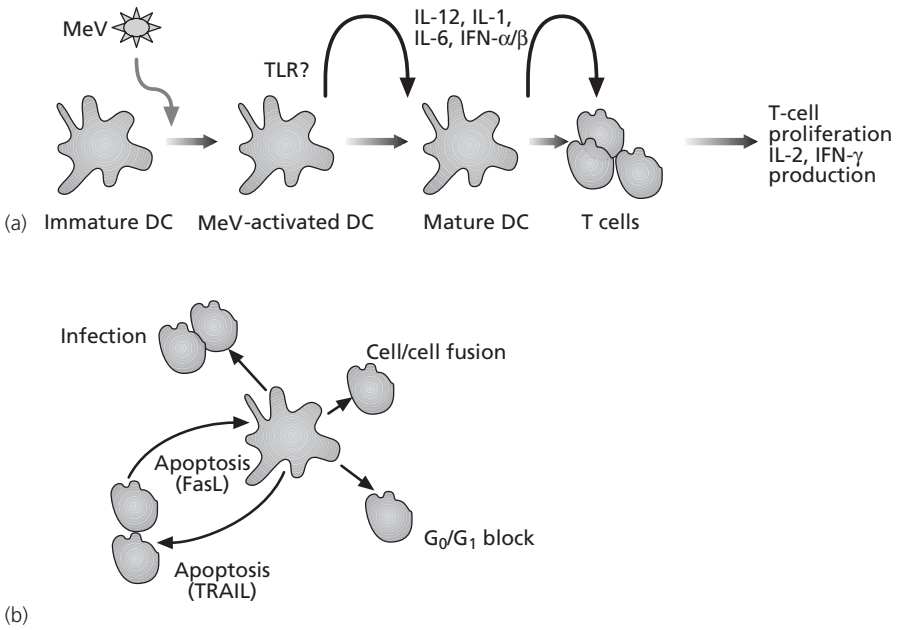

Figure 7 *Impact of measles virus (MeV) on dendritic cell (DC) maturation and T-cell activation.* **(a)** *Immature DCs, are activated and mature upon infection or surface interaction with MeV as indicated by up-regulation of MHC and costimulatory molecules and the induction of cytokines, which act as autocrine and paracrine factors further triggering maturation. Both cell–cell contacts and cytokines activate and shape T-cell responses, and this may effectively occur after uptake, processing, and presentation of viral components early after DC infection.* **(b)** *With on-going viral replication, MeV-infected DCs promote DC/T cell fusion and T-cell infection, inhibition of T-cell proliferation by expressing high levels of the MeV glycoprotein complex and T-cell apoptosis by TRAIL expression. DC depletion may result from fusion or FasL-induced apoptosis by T cells.*

Table 2 *Characteristic findings related to MeV-induced immunosuppression*

	Findings
In vivo	Susceptibility to opportunistic infections
	Loss of delayed type hypersensitivity responses
Ex vivo	Leukopenia
	MeV-infected peripheral blood mononuclear cells
	Cytokine imbalance
	Long-term suppression of IL-12 production
	Loss of proliferative responses of lymphocytes
In vitro	
Antigen-presenting cells	Apoptosis and cytotoxicity
	Infection and fusion
	Aberrant terminal maturation
	Suppression of stimulated IL-12 release
B cells	Growth arrest
	Production of inhibitory soluble mediators
T cells	Depletion by aberrant homing and apoptosis
	Production of soluble inhibitory mediators
	Loss of stimulated proliferative responses due to infection or cell-surface signaling by the MeV glycoprotein complex

impaired production of IL-12 from these cells may occur (Atabani et al. 2001; Fugier-Vivier et al. 1997; Servet-Delprat et al. 2000b). The role of IL-12 depletion in MeV-induced immunosuppression is, however, unclear as yet (Hoffman et al. 2003). In MeV-infected DC/T cell cocultures, fusion and apoptosis of both DC and T cells was seen. While the latter has been linked to MeV-mediated upregulation of TRAIL on DC and FasL on T cells (Servet-Delprat et al. 2000a; Vidalain et al. 2000), the first is exerted by the MeV glycoprotein complex expressed on DC at high levels late in infection (Ohgimoto et al. 2001). It is, however, also evident that MeV-infected DC fail to stimulate allogenic T-cell proliferation and actively inhibit mitogen-stimulated expansion without grossly interfering with the viability of these cells (Fugier-Vivier et al. 1997; Grosjean et al. 1997; Klagge et al. 2000; Schnorr et al. 1997b; Steineur et al. 1998). The inhibitory phenotype of MeV-infected DC has been linked to direct negative signaling to T cells via the MeV glycoproteins rather than to soluble inhibitory mediators (Dubois et al. 2001; Klagge et al. 2000) (Figure 7b). Expression of the MeV glycoprotein complex on infected or transfected cells or virions was found necessary and sufficient to induce a state of proliferative unresponsiveness to polyclonal and CD3/CD28 stimulation in lymphocytes (Niewiesk et al. 1997a; Schlender et al. 1996; Schneider-Schaulies et al. 2001).

For this to occur, surface contact of uninfected cells and UV-irradiated virions or cells expressing a complex of H protein and proteolytically activated F protein is required, while soluble inhibitory mediators are not involved (Weidmann et al. 2000a,b) (Figure 8a). Contact-mediated inhibition is not associated with the induction of apoptosis, but rather T-cell arrest in the late G_1 phase of the cell cycle as determined by characteristic deregulations in the expression levels and activity of S-phase entry control proteins (Naniche et al. 1999; Niewiesk et al. 1999, 2000; Schnorr et al. 1997a). Not surprisingly, intracellular signaling pathways in T cells are directly targeted by cell surface interaction with MeV. Thus, IL-2- or anti-CD3/CD28-dependent activation of the phosphoinositol-3-kinase/Akt kinase pathway, which is involved in regulating cell cycle control proteins, is disrupted after MeV contact (Avota et al. 2001) (Figure 8b). There is evidence that the N protein may also contribute to suppression of lymphocyte functions. It was found to inhibit antibody production in vitro by binding to FcγIIR on B cells (Ravanel et al. 1997), and to induce sustained calcium influx, as well as a G_0/G_1 arrest of thymic epithelial cells and other cell types (also including lymphocytes) by binding to an unknown, ubiquitously expressed receptor (Laine et al. 2003).

Persistent measles: CNS infections

MEASLES INCLUSION BODY ENCEPHALITIS (MIBE)

As this condition is confined to patients with underlying immunodeficiencies, it is not usually accompanied by intrathecal antibody synthesis. The unprotected cells develop both nuclear and cytoplasmic massive inclusion bodies consisting of virus nucleocapsids (Roos et al. 1981). Infectious virus has only been occasionally isolated by conventional methods from brain tissue, suggesting defects in replication (Baczko et al. 1988, 1993; Ohuchi et al. 1987; Roos et al. 1981). This assumption has been supported by immunohistological and molecular biological studies in MIBE (Baczko et al. 1988). In brain tissue, only N and P, but not the envelope proteins were consistently detected. In

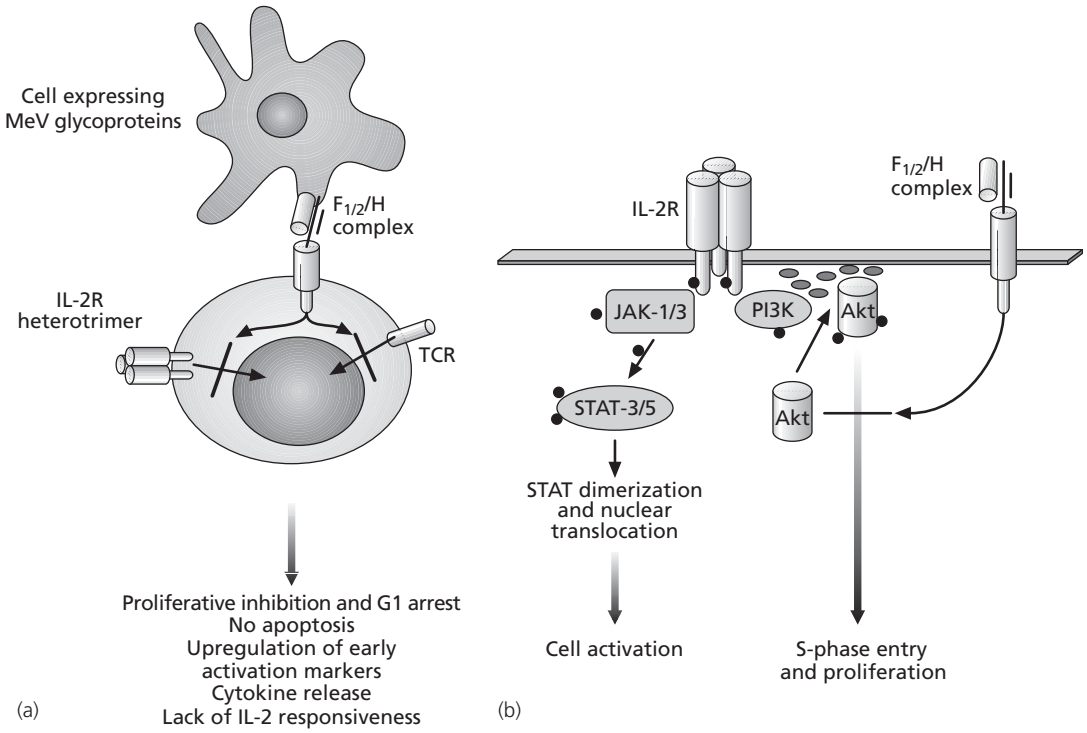

Figure 8 *Mechanisms of MeV contact mediated T-cell inhibition and consequences.* **(a)** *The MeV $F_{1/2}$/H complex induces by interaction with an, as yet unknown, receptor proliferative arrest in lymphocytes, which causes their arrest in the G1 phase of the cell cycle. In primary T cells, mitogen-induced expression of activation markers and cytokines is not affected. The IL-2R heterotrimer is expressed to normal levels, yet exogenous IL-2 does restore T-cell proliferation.* **(b)** *Signaling via the interleukin 2 receptor (IL-2R) on T cells involves phosphorylation of the cytoplasmic domains of its β- and γ-subunits. This provides docking sites for the Janus kinases JAK-1/3 which, when autophosphorylated, provide docking sites for and phosphorylate STAT-3 and STAT-5, which then dimerize and translocate to the nucleus. IL-2R signaling also activates phosphatidylinositol 3-kinase (PI3K), which catalyzes phosphorylation of inositol-phosphates. As second messengers, these recruit the Akt kinase to the cell membrane where this kinase is phosphorylated and subsequently regulates the activity of downstream targets. In T cells, this pathway was found to be particularly important for S-phase entry and proliferation. Contact with the MeV $F_{1/2}$/H complex abolishes the IL-2-dependent activation of the PI3K/Akt pathway, but not that of the JAK/STAT pathway.*

contrast, the mRNAs specific for the viral proteins were detectable in brain-derived total RNA samples with the mRNAs for the envelope proteins being under-represented. The latter failed to direct the synthesis of the corresponding proteins in vitro and this restriction was partially explained by a high rate of mutations distributed over the entire MeV genome (Cattaneo et al. 1988a,b; 1989b). Defects in MeV mRNA transcription and envelope protein synthesis apparently did not largely affect the activity of the RNP complex which spread to different areas of the patient's brain. As infectious virus particles may never be formed due to the restriction of the envelope proteins and giant cell formation has never been observed, the spread is thought to occur by microfusion events.

SUBACUTE SCLEROSING PANENCEPHALITIS (SSPE)

MeV was first implicated in the etiology of this disease by immune fluorescence in 1967 and this has since been confirmed by electron microscopy, immunoelectron microscopic (IEM) methods, and finally by the successful rescue of virus by co-cultivation techniques. Despite this, mechanisms underlying the transport of virus into the CNS, establishment and initial maintenance of persistence, and production of disease are still largely unknown. The virus is thought to gain entry to the CNS during viremia in acute measles by infected lymphocytes or infection of cerebral endothelial cells (Kirk et al. 1991; McQuaid and Cosby 2002), but once there, replication most likely proceeds only slowly. It is also not known to what extent virus replication per se is responsible for the development of lesions, or what part is played by the immune system.

Virological aspects

In SSPE, free infectious virus has never been isolated either from the brain or from CSF, and histopathological examinations have consistently failed to reveal the morphological changes associated with virus maturation. As with MIBE, giant cells and thickening of the plasma membrane at points of budding were never seen suggesting the absence of viral glycoproteins. Viral nucleocapsids present in the cytoplasm are randomly scattered and show no sign of regular alignment beneath the plasma membrane. As budding viral particles and infectious virus are not detected, the infection may spread slowly in a strictly cell-associated manner. The ability of MeV to spread transneuronally in the absence of virus production has recently been confirmed in tissue culture and this can occur in the absence of CD46 (Duprex et al. 1999b, 2000; Ehrengruber et al. 2002; Lawrence et al. 2000). Nevertheless, CD46, which is expressed on certain brain cells such as oligodendrocytes and a subset of neurons, is apparently down-regulated from MeV-positive cells in lesions (McQuaid and Cosby 2002; Ogata et al. 1997).

In SSPE brain sections, only the expression of the MeV N and P proteins and not that of the envelope proteins was consistently detected in infected cells (Liebert et al. 1986). Molecular biological studies on SSPE brain tissue revealed extensive transcriptional and translational alterations affecting mainly MeV envelope-protein specific genes (Baczko et al., 1986, 1988; Cattaneo et al. 1987, 1988b). As in MIBE, mRNAs specific for these genes were detected at only low copy numbers and were highly impaired in directing in vitro protein synthesis. A high rate of mutations was found all over the MeV genome. While the *M* gene was most affected, the *F*, *H*, *P*, and *N* genes were mutated to about the same extent, and the L gene was most conserved (Cattaneo et al. 1988a,b; 1989b). Mutations introduced were either point mutations, or appeared as clustered transitions which are thought to result from the activity of a cellular enzyme complex that actively modifies viral genetic information (Baczko et al. 1993; Cattaneo et al. 1988b). As revealed by detailed analyses, mutated MeV genomes may clonally expand in SSPE (Baczko et al. 1993). As a result of either of these events, translation of viral mRNAs was completely abolished or led to the synthesis of truncated or unstable MeV proteins. With respect to the overall high degree of conservation of the *F* gene within all MeV strains known (Rima et al. 1995), it is remarkable that truncations, mutations or deletions in the cytoplasmic domain of the F protein are almost universal (Billeter and Cattaneo 1994). These findings explain the absence of infectious MeV particles and cell fusion in infected SSPE brain tissue, which both require biologically active MeV envelope proteins. Virus can, however, occasionally be rescued from brain tissue obtained post mortem by cocultivation (Griffin and Bellini 1996). Some of these SSPE isolates have been proven invaluable tools to study virological parameters and specific genetic defects in SSPE, others, however, most likely represent contaminations and are in fact ordinary laboratory MeV strains (Rima et al. 1995). It is still unclear whether true SSPE isolates represent the dominant MeV population in the infected brain or rather small subpopulation of replication/maturation competent viruses or revertants that have been selected by the isolation procedure.

Factors involved in the establishment of persistence by a nondefective MeV in brain tissue are largely unknown. Differential interaction of the M protein with the viral RNP has been suggested for negative regulation of MeV transcription (Suryanarayana et al. 1994). There is, however, evidence that factors intrinsic to the host cell in the brain intimately control and downregulate the efficiency of MeV gene expression. In tissue culture experiments with cells of neural origin and in brain material of experimentally infected animals, evidence has been provided that intracellular factors control the efficiency of

MeV replication (Schneider-Schäulies et al. 1989). These may include unknown factors associated with brain cell differentiation (Schneider-Schäulies et al. 1993; Yoshikawa and Yamanouchi 1984), as well as the type I IFN-inducible MxA protein, which negatively regulates MeV transcription in brain cells, but not in monocytes and fibroblasts (Schneider-Schäulies et al. 1994; Schnorr et al. 1993). In addition, the cellular enzyme activity actively modifying the primary sequence of viral RNAs has been demonstrated in these cells. Thus, intracellular factors present in brain cells act to slow down viral replication after primary infection thereby preventing a rapid host-cell destruction. This may even be enhanced by virus neutralizing antibodies which were found to down-regulate MeV transcription by activating as yet unknown signaling cascades (Schneider-Schaulies et al. 1992; Segev et al. 1994). There is also evidence that MeV may regulate intracellular signaling cascades in a cell type-specific manner since it activates the transcription factor NF-κB in glial, but not neuronal cells (Dhib-Jalbut et al. 1999). Since activation of NF-κB is an essential prerequisite for the induction of most genes associated with cellular defense (such as proinflammatory cytokines), this may interfere with initial control of infection. Differential regulation of cytokines produced in primary and persistently infected glial cells has also been documented (Schneider-Schäulies et al. 1993). Whether these control mechanisms are efficient in establishing and maintaining persistent infection or other factors, such as the introduction of mutations into the viral genome are required, has not been resolved.

Critical components for disease progression and clinical appearance also remain speculative. Infection-induced loss of brain cells is likely to contribute, and this may occur to a certain extent during the asymptomatic phase. Since this is not brought about by giant cell formation, apoptosis as seen in neuronal and macroglial cells both in SSPE brain tissue and experimental CNS infection in mice is likely to be important (Anlar et al. 1999; Manchester et al. 1999). There is, however also evidence from in vitro experimentation that MeV infection does not grossly interfere with brain cell viability, but may specifically target expression of proteins required for luxury functions (Meissner and Koschel 1995).

Immunological aspects

Studies performed in SSPE patients did not reveal any evidence for a global defect in immune responses, which could account for the establishment of a persistent MeV CNS infection. A virus-specific humoral hyperimmune response is pathognomonic for SSPE. There is a significant production of MeV-specific antibodies by plasma cells residing in the CNS leading to marked elevations in the level of CSF immunoglobulin (Connolly et al. 1971). As opposed to the polyclonal response observed in serum, MeV-specific antibodies produced in the CNS are of restricted heterogeneity leading to the appearance of oligoclonal immunoglobulin bands (Doerries et al. 1988). This suggests that antibody in the CSF is made locally by lymphocytes that have invaded this compartment from the periphery in response to antigens present in the CNS. In serum specimens, antibodies of the IgG and IgD type with specificity to all MeV proteins are present, although recognition of the M protein is low or sometimes absent, whereas antibodies in CSF samples, which are of the IgG, IgA, and IgD types, generally fail completely to detect M protein (Hall et al. 1979). Studies performed on the cellular immunity in SSPE revealed that MeV-specific lymphoproliferation is similar to that of normal measles-seropositive individuals. Similarly, other measures of cellular immunity such as skin test responses to recall antigens and proliferative responses to mitogens are normal (Dhib-Jalbut et al. 1989). The mononuclear inflammatory response in the brain includes $CD4^+$ and $CD8^+$ T cells, monocytes, and Ig-secreting B cells (Nagano et al. 1991). MHC class I and class II expression is increased in the brain, and β2 microglobulin, soluble IL-2R, and soluble CD8 are elevated in CSF (Mehta et al. 1992).

EPIDEMIOLOGY

Measles infections are transmitted via aerosol or droplet exposure generated from a cough or sneeze or via contaminated fomites. The disease is so highly contagious that susceptible individuals who come into close contact with measles patients have a 99 percent probability of acquiring the disease. Measles disease is believed to have emerged as human populations began to organize into larger communities. These communities had sufficient birth cohorts that provided a renewable source of susceptible individuals, thus permitting sustained endemic transmission of the virus within the population. The epidemiology of measles virus differs in unvaccinated versus vaccinated populations. In the prevaccine era, greater than 90 percent of individuals would acquire measles infections before 10 years of age. In unvaccinated populations, measles causes periodic epidemics with interepidemic periods of 2–5 years. These periods decrease as population size and density increase, which is directly related to the availability of susceptible individuals for disease transmission.

In vaccinated populations, the interval between measles outbreaks increases and sufficiently high levels of vaccination can interrupt endemic transmission. With vaccination, the age distribution of cases is determined by which groups are likely to lack vaccine or measles induced immunity. In the United States, an extensive effort to achieve high levels of first dose measles vaccination at 12 to 15 months of age, and addition of a recommended second dose of vaccine in school-aged children has resulted in a decrease in reported measles cases from 400 000 to 500 000 per year in the 1960s to a

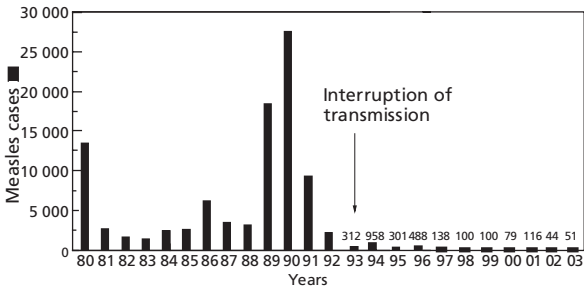

Figure 9 *The number of reported cases of measles per year ranging from 1980 to 2003. The arrow indicates the year of interruption of transmission based on no reported cases of measles for a 12-week period in 1993.*

record low of approximately 100 cases per year from 1998 to 2003 (Figure 9) (CDC 2004). It is likely that endemic transmission of measles in the United States was interrupted in 1993 and subsequent cases have occurred through periodic introduction of measles from other countries followed by limited spread (Bellini and Rota 1998; Rota et al. 2004). Given widespread international travel, measles will continue to occur even in highly vaccinated populations until global eradication is achieved.

Measles remains a formidable disease of children in many areas of the world. The World Health Organization estimates that over 30 million cases occur annually. Approximately 775 000 measles-associated deaths occur annually worldwide, and about 500 000 deaths occur in Africa alone (WHO 1999). In marked contrast, effective use of available live-attenuated measles vaccines, and a variety of multidose vaccination strategies have combined to eliminate measles in many large geographic regions including the Americas, many Scandinavian countries, and the United Kingdom. The WHO and United Nations Children's Fund have announced a strategic plan aimed at enhancing measles control and reducing global mortality by 50 percent based on the 1999 data by 2005. Most regions of the WHO have established strategic plans and tentative time-lines for measles elimination, but a decision to move to global eradication has not yet been made.

DIAGNOSIS

Before the widespread use of measles-containing vaccines, acute measles was diagnosed on the basis of the distinctive symptoms and laboratory confirmation was seldom necessary. As vaccination programs expand, the diagnostic acumen of many physicians to recognize acute measles has decreased (Helfand et al. 2004). Moreover vaccination itself has led to the emergence of unusual presentations and milder forms of measles. For these reasons and the fact that more patients are either being placed on immunosuppressive regimens, or have immunosuppressive illnesses such as acquired immune deficiency syndrome (AIDS), the need for laboratory diagnosis/confirmation of MeV has increased.

Microscopy

On direct examination, production of multinucleate giant cells with inclusion bodies is pathognomonic for measles during the prodromal phase. Such cells are detectable in the nasopharyngeal secretions (NPS). Clear identification of giant cells and Cowdry inclusion bodies is facilitated if the smear is first fixed in formalin and then stained with hematoxylin or eosin. Both direct and indirect immunofluorescence (IF) have been widely used to stain cells shed in nasal secretions, although it may be necessary to remove antibodies that already coat virus antigens with a low pH buffer. Stained cells include macrophages and ciliated cells, as well as giant cells. Urinary sediment cells have also been examined with a high degree of success. IF-positive cells may be shed in the urine from 2 days before to up to 5 days after the appearance of the rash. This method may therefore be more applicable in later stages than examination of NPS specimens. Such cells may also be present in the urine 4–16 days after vaccination with the live vaccine. IF is useful for the diagnosis of measles in the pre-eruptive phase. Immunoperoxidase histochemical stains have also been used, and the use of monoclonal antibodies has improved sensitivity and reliability of virus detection (Zaki and Bellini 1997).

Serology

In common with other infections, diagnosis of measles may be made if antibody titers rise by more than four-fold between the acute and the convalescent phases or if measles-specific IgM is found. Traditional antibody tests such as hemagglutination inhibition (HI), plaque-reduction neutralization (PRN), and enzyme-linked immunoassay (EIA) have been used extensively in the serologic diagnosis of measles. Because of the availability of sensitive and specific commercial kits, EIA has become the most widely used test format. These tests also have the ability to measure measles-specific IgM, as well as IgG responses and therefore have particular importance in diagnosis as well as measles control programs. Some of the available kits were found to have sensitivities and specificities that compared favorably with plaque reduction neutralization (de Sousa et al. 1991; Ratnam et al. 1995). Most laboratories have trained personnel and are already equipped to run EIA tests.

The recommended laboratory method for the confirmation of clinically diagnosed measles is a serum-based IgM EIA. Several serum-based capture and indirect IgM EIAs are now commercially available for use by public health, clinical, and commercial laboratories and, for the

most part, are used worldwide. The network of laboratories within the Pan American Health Organization supported the measles eradication efforts throughout the Americas using EIA as the primary confirmatory assay. The WHO Global Measles Laboratory Network has also recommended the use of the IgM EIA for the laboratory diagnosis of measles. The EIA tests can be done using a single serum specimen, are relatively rapid (2–6 h) and simple to perform, and can be used to diagnose acute measles infection from the time of rash onset until at least 4 weeks after rash onset. Thus, the IgM EIAs fulfill all the basic criteria for the accurate, effective, and efficient diagnosis of measles. Both indirect and IgM capture formats have been used (Erdman et al. 1991; Hummel et al. 1992). Though IgM capture is often regarded as the more sensitive format, studies that have compared the capture and indirect formats found that some of the commercial indirect EIA kits had sensitivities and specificities that equaled those of the capture format (Arista et al. 1995; Ratnam et al. 2000).

Isolation and detection of viral RNA

Until recently, the lack of sensitive cell lines for efficient growth of measles virus made cell culture isolation difficult, even when optimal specimens for virus isolation were available. Previous tissue culture and cell lines, such as primary monkey kidney cells and Vero cells, were considered to be permissive for measles infection. However, it is now recognized that these cells do not possess the appropriate receptor(s) for most wild-type viruses, which explains the low frequency of measles isolation when using these cell types. An Epstein–Barr virus transformed marmoset B lymphocyte cell line (B95a) was demonstrated to be approximately 100 to 1 000 times more sensitive than Vero cells and is currently the cell line of choice for measles virus isolation (Kobune et al. 1990). Attempts at measles isolation indicated that the best success is attained when specimens are collected within 0–5 days of rash onset. Although virus isolation has never been used for routine diagnosis of measles infection, use of the method is encouraged particularly in outbreak settings where there is a requirement for molecular epidemiologic data.

For virus isolation, washings and swabs are collected and mixed with buffered salt solution (pH 7.2) containing antibiotics. Urinary sediment cells are collected by low-speed sedimentation and treated similarly. Measles can be isolated directly from blood, but efficiency is increased if lymphocytes are first separated on a Ficoll gradient and stimulated with mitogen before use. MeV isolated in B95a cells differed in some biological properties from those adapted to Vero cells, suggesting MeV is subject to host cell-mediated selection. It is therefore recommended to include attempts in these cell lines in MeV isolation. Cytopathic effects (CPE) develop usually between 48 h and 15 days, and consist either of a broad syncytium or of a stellate form. Both types reveal inclusion bodies which may be present in both nucleus and cytoplasm. It is not known what governs the different forms of CPE, but the availability of cellular nutrients as well as the type of virus has an effect. Uninoculated identical cultures should also be maintained as controls. If CPE is slow or not clear, it is possible to test whether the cells contain MeV antigens or RNA by appropriate detection methods. RT-PCR-based detection of viral RNA is best applied in specific instances, such as suspected infection of the immunosuppressed in the absence of rash when only limited antiviral immunoglobulins might be expected, developing pneumonia without a rash, or unexplained encephalitis. Finally, both techniques can be attempted as a means of retrospective diagnosis using tissue obtained post mortem. RT-PCR analyses using MeV *N* and/or *F* gene-specific primers are the most commonly performed tests and employ a wide variety of specimens from which RNA is extracted and used as template, including serum, nasopharyngeal aspirates, urine sediment cells. Tissue samples including lung, kidney, skin, and brain are also amenable for testing by RT-PCR following appropriate chaotropic salt treatment and nucleic acid extraction.

Two new approaches show promise in terms of alternatives to specimen collection for the diagnosis of measles: the use of oral fluid and the use of blood spots on filter paper. Oral fluid samples have been used both for detection of measles-specific IgM and IgG, as well as rubella and mumps (Helfand et al. 1996; Perry et al. 1993). This technique is already being used for routine measles surveillance in the UK (Jin et al. 2001). The use of oral fluid samples has appeal because the technique is noninvasive, it can be used for rubella testing, it does not require processing of the sample in the field, and it may be possible to detect not only measles-specific IgM, but measles virus genome for molecular characterization (Riddell et al. 2001). However, oral fluid samples have the disadvantage that the specimens often have heightened background reactivity in commercial assays, or the commercial assays are not sufficiently sensitive when oral fluid specimens are used. Both factors make the use of oral fluid specimens less useful in settings with low measles incidence.

Like oral fluid samples, blood spots collected on filter paper do not require processing in the field, a cold chain does not appear necessary, they can be used to test for rubella as well as for measles (Condorelli et al. 1994, 1998; Helfand et al. 2001), and they can be used for molecular characterization of the measles virus genome (de Swart et al. 2001), although virus isolation would not be possible. In addition, the eluted serum from blood spots can likely be tested in commercially available measles EIA assays without the loss of sensitivity and specificity (de Swart et al. 2001; Helfand et al. 2001), making this technology very attractive for widespread use. Although

still considered an invasive technique as a method for sample collection, fingerstick is often more acceptable to parents than phlebotomy (Wassilak et al. 1984).

TREATMENT

Measles is an acute self-limiting disease, which, in the absence of complications, will run its course without the need for specific intervention. Treatment is supportive and there are no proven effective antiviral compounds available. Infection of the undernourished, the immunocompromised or children suffering from chronic debilitating diseases is more serious. Such patients as well as children of less than 1 year of age and pregnant women after household contacts can be protected by the administration of human anti-measles gammaglobulin (0.25–0.5 ml/kg). If this is given within the first 3 days after exposure, it is usually effective (CDC 1989). The effectiveness is diminished if the globulin is given 4–6 days after exposure, and abolished if more than 6 days have elapsed. Ribavirin has been used to treat pneumonitis and SSPE (Mustafa et al. 1993). Respiratory tract infections cause considerable damage to the ciliated epithelium and this may lead to superimposed bacterial infections. In the case of a pneumonia it is sometimes difficult to distinguish between primary viral infections and the superimposed bacterial infection. In any case, treatment with antibiotics is required.

Treatment of acute measles postinfectious encephalitis is only symptomatic and supportive, and does not differ from any other postinfectious encephalitis. Careful attention to fluid and electrolyte balance is essential. Seizure control requires anticonvulsive drugs. Application of steroids has not been shown to be beneficial. No specific therapy is known for SSPE. A variety of approaches have been attempted, but as yet no convincing results effects have been demonstrated and almost all cases have proved fatal. Evaluation of the effectiveness of treatment is extremely difficult. First, the course of SSPE is highly variable and spontaneous remissions are common. Secondly, SSPE is a rare disease, and clinical trials are therefore inevitably based on a very small number of patients and interpretation is difficult. Isoprinosine (inosiplex) and interferon (also applied in combination) have been widely used for treatment of SSPE without, however, preventing the lethal outcome of the disease (Gascon 2003). In the case of isoprinosine, it seems likely that treatment may lengthen survival time if given early in the disease.

PREVENTION

Vaccination with measles-containing vaccine is the only effective way to prevent measles infections. The PAHO region of the WHO has effectively eliminated measles using live-attenuated measles vaccine. Although the vaccine strategies in the PAHO member countries markedly varied, all strategies provided vaccinees with the opportunity to receive two doses of vaccine (de Quadros et al. 2004). Following a resurgence in measles disease between 1989 and 1991, the United States adopted a two dose vaccination schedule (American Academy of Pediatrics 1998). The first dose is administered at 12–15 months of age, and currently the second dose can be given any time between 4 weeks later and school entry. At present, the vaccine coverage in the US is estimated to be 93 percent (Hutchins et al. 2004). As a result of the improved immunization strategy, the number of reported measles cases has dramatically dropped (Figure 9) and most of the reported cases can be attributed to importations. In Germany and the UK, where vaccination is not mandatory, philosophical opposition to and distrust of vaccination has led to a lower acceptance rate and less dramatic results have been achieved.

In developing countries, the consequences of MeV infection are most severe. Factors, such as the presence of maternal antibody, underlying infectious diseases, and malnutrition, profoundly interfere and confound vaccine efficacy in age groups most vulnerable to measles. Moreover, large influxes of migrating refugees from areas beset by conflict or natural disaster have resulted in the re-introduction of measles into populations that have undergone mass vaccination efforts, thus complicating the assessment of vaccine efficacy. Although the live-attenuated measles-containing vaccines have been successfully used to control and eliminate measles in the Americas and elsewhere (see below), the experience in Africa has led some to consider development of alternative vaccines, such as high-titered vaccines, DNA-based vaccines with or without adjuvants, thermostable dried powder vaccines, and more. With the exception of the high-titered vaccines, which are no longer recommended by the WHO following their association with adverse outcomes (Aaby et al. 1993; Holt et al. 1993), none of the other alternatives have been clinically tested. Nonetheless, any vaccine used in mass vaccination campaigns must be safe, as measles is not normally a life-threatening illness, efficacious, and affordable for mass administration. Its effectiveness should also be long-lasting, if not life-long.

Live vaccine

The first attenuated vaccine strain was the Edmonston B strain produced by serial passage of the virus in human kidney cells, human amnion cells, chick chorioallantoic membrane and, finally, chicken embryo fibroblasts (Rota et al. 1994). This vaccine was administered intramuscularly or subcutaneously 12–18 months after the disappearance of maternal antibodies. Vaccination resulted in 95 percent seroconversion of recipients, but side-effects of mild measles (fever and rash) were common (5–10 percent). Consequently, the vaccine was administered along with immunoglobulin (Ig) to modify the side-

effects (Markowitz and Katz 1994). The side-effects and necessity to provide Ig led to the development of the further attenuated and less reactogenic Schwarz and Moraten strains. These were derived from the Edmonston B vaccine by further passage in the chick embryo at lowered temperature. Further Medical Research Council (UK) trials demonstrated that these were indeed less reactogenic and the incidence of postvaccination febrile convulsions was reduced from 7.7 to 1.9 per 1 000 recipients. Both vaccines produced a 95 percent seroconversion rate, although antibody titers induced by the Schwarz strain declined more rapidly than those produced in response to the Moraten strain but remained at protective levels.

In recent years, the Edmonston B vaccine strain was further passaged in human diploid cells. This vaccine, referred to as Edmonston Zagreb strain, has been shown to produce higher seroconversion rates than the Schwarz vaccine when administered at the same age. Similar observations have been made with the AIK-C vaccine, produced in Japan, but whose lineage stemmed from the Edmonston A virus. All WHO measles vaccines that are currently in use are derived from Edmonston Enders A or B seed stocks. The attenuated strains now in use are so reduced in virulence that encephalitis has only been noted in about one in 1 million vaccine recipients as compared to one per 1 000–5 000 children with natural measles. The measles vaccine is administered subcutaneously usually between the ages of 9 and 20 months for primary vaccination. Humoral immune responses, as defined by HI, NT, and enzyme-linked immunosorbent assay (ELISA), are good and protective as long as the vaccine is given after waning of the maternal antibodies. As with acute measles, the major isotype of MeV-specific antibodies is IgG1. Levels of antibodies induced are generally lower than after natural infection and may decay more rapidly, however, are still measurable in most individuals 30 years after immunization in the absence of boosting infections (Dine et al. 2004). Activation of cell-mediated immunity is generally thought to be similar to that of acute measles in that both MeV-specific $CD4^+$ and $CD8^+$ T cells are stimulated, although CTL-responses after restimulation in vitro are considerably lower than after natural infection. Also similar as with acute measles, administration of live measles vaccine is associated with transient lymphopenia, loss of DTH skin test responses to recall antigen, and decreased in vitro proliferative responses to mitogens. Both leukopenia and atypical lymphocytosis have also been found after revaccination.

Effectiveness of vaccination in the control of measles

In the prevaccine era, an estimated 4–5 million cases occurred annually in the USA and by the age of 15 years 95 percent of the population had seroconverted. Following the rigorous implementation of the MeV vaccination program in the United States, the case reports fell dramatically from 500 000 annually to 26 000 in 1978 and 1 500 in 1983. From 1984 to 1988 only 3 700 cases were reported (Figure 9). As a result of measles vaccination, the mortality and PIE have also declined and the available experience indicates that SSPE can also be prevented by measles vaccination (Halsey 1990). However, in 1989 and 1990 a dramatic increase in acute measles cases was observed in the USA which rose in 1989 to 18 193 and in 1990 to 27 786 cases (Figure 9) (Atkinson et al. 1992). The two major causes for this resurgence of measles were the unappreciated low vaccine coverage among preschool-aged children, particularly in urban settings, and vaccine failure (waning immunity) in a low percentage of school-aged children who received only a single dose of vaccine. As a result of this measles epidemic and to address the issue of possible waning immunity, the American Academy of Pediatrics (AAP) and the Immunization Practices Advisory Committee of the USA (ACIP) recommended a change from a one-dose to a two-dose schedule for measles vaccination, as discussed earlier. In 1998, both groups issued a uniform recommendation for a second dose before school entry, and further recommended that all school-aged children receive a second dose of vaccine before 2001 (American Academy of Pediatrics 1998; Watson et al. 1998). The elimination of measles in the USA has taken a strong political and social commitment, uniting the efforts of many professional groups such as the ACIP, AAP, American Academy of Family Physicians (AAFP), state and local governments, and a number of community-based organizations. In 1999, single dose coverage at 2 years and at school entry was 92 and 98 percent, respectively. Seventy percent of school-aged children were estimated to have received two doses of vaccine in 1998 (CDC 2000; Kolasa et al. 2004). The two-dose schedule is only one strategy used to ensure high vaccine coverage in the quest for measles elimination. PAHO has used live-attenuated MeV in a strategy known as keep-up, catch-up, follow-up. This strategy combines routine vaccination (keep-up) with mass vaccination campaigns (catch-up), and 4-year follow-up campaigns (follow-up) (de Quadros et al. 1996). Both this schedule and the two-dose schedule employ the live-attenuated vaccine and are predicated on effective and efficient implementation of routine immunization programs. Furthermore, both strategies provide at least a second immunization opportunity for the vaccinee. Many countries in various regions of the WHO have adopted different variations of the two opportunities for immunization strategy for the interruption of measles transmission with remarkable results (Strebel et al. 2004). When used in conjunction with the two opportunities for measles vaccination, the current live-attenuated measles vaccine has proven to be efficacious, effective, and safe. Initial vaccination can be

administered at 6 months of age to children living in high-risk areas (areas with a large inner-city urban population where more than five cases among preschool-aged children occurred during each of the last 5 years or with recent outbreaks among unvaccinated preschool-aged children). Vaccination at ages younger than 12 months is associated with reduced efficacy, thus a second dose of vaccine is critical to ensure protection for those children. In these cases, the second dose should be administered before the determined average age of onset of natural measles for the region/country.

Side-effects of live vaccination, adverse reactions, precautions, and contraindications

The vaccine has an excellent record of safety. Although on rare instances a transient rash or low-grade fever are observed after 5–12 days in some vaccinees, these remain otherwise asymptomatic as for the vast majority of recipients. As with the administration of any agent that can induce fever, some children may have a febrile seizure. Although children with a history of seizures are at increased risk for developing idiopathic epilepsy, febrile seizures following vaccinations do not increase the probability of subsequent epilepsy or neurologic disorders. Most convulsions following measles vaccination are simple febrile seizures, and they affect children without known risk factors. Nevertheless, parents of children who have a personal or family history of seizures should be advised of the small increased risk following measles vaccination which is, however, by far outweighed by the benefits of the protective effects. CNS conditions, such as encephalitis and encephalopathy, have been reported with a frequency of less than one per million doses administered, an incidence which is lower than that of encephalitis of unknown etiology. This finding suggests that the reported severe neurologic disorders temporarily associated with measles vaccination were not caused by the vaccine. Live measles vaccine should not be administered to women who are, or are considering becoming, pregnant within the next 3 months because of the theoretical risk of fetal infection. The decision to administer or delay vaccination because of a current febrile illness depends on the cause of the illness and the severity of symptoms. Hypersensitivity reactions following the administration of live measles vaccine are rare and usually occur at the injection site. Vaccine is contraindicated in persons with a history of anaphylactic reactions to eggs or gelatin following ingestion. Individuals who have experienced anaphylactic reactions to neomycin should not be given the vaccine (Duclos and Ward 1998).

Replication of vaccine viruses can be enhanced in persons with immune-deficiency diseases and in those with immunosuppression, as occurs with leukemia, lymphoma, generalized malignancy, or therapy with alkylating agents, antimetabolites, radiation, or large doses of corticosteroids. Thus, patients with such conditions or therapies (except for HIV infection) should not be given live measles vaccine. Short-term corticosteroid therapy does not contraindicate live measles vaccination. The increasing number of infants and preschoolers with HIV infection in certain countries has directed special attention to the appropriate immunization of these children. Asymptomatic children in need of measles live vaccination should receive it without prior evaluation of HIV infection state. Moreover, vaccination should be considered for all symptomatic HIV-infected children, including those with AIDS, since measles in these children can be severe. Limited data on measles vaccination among both asymptomatic and symptomatic HIV-infected children indicate that the vaccine has not been associated with severe or unusual adverse events, although antibody responses have been unpredictable (Moss et al. 1999, 2003). Exposed symptomatic HIV-infected (as well as other immunocompromised) persons should receive high doses of measles Ig regardless of their previous vaccination status.

IDENTIFICATION OF THE VIRUS AND CLASSIFICATION

As a disease, mumps has been known for centuries (Gordon and Kilham 1949). A population of roughly 200 000 people is needed to sustain mumps infection and this density was first achieved about 4 000 to 5 000 years ago (Carbone and Wolinsky 2001). The first description of a mild epidemic illness with swelling in front of the ear, sometimes accompanied by painful swelling of the testes, is accredited to Hippocrates in the fifth century BC. The name mumps may be derived from the Old English verb meaning 'to sulk' or from the Scottish verb meaning 'to speak indistinctly' (Gershon 1995).

As early as 1908 Granata suggested, from experiments in rabbits, that mumps disease was caused by a filterable agent (Granata, cited in Wollstein 1916). However, it was Johnson and Goodpasture (1934) who first induced parotitis in rhesus monkeys by inoculating fresh saliva from acute mumps cases directly into Stensen's duct, and then passed the infection to further monkeys by inoculation of a sterile parotid gland extract by the same route. A major step forward was the growth of monkey-passaged mumps virus in the yolk sac, amniotic sac, and allantoic sac of developing chick embryos (Habel 1945; Levens and Enders 1945). This was followed by primary isolation from human saliva (Beveridge et al. 1946) and cerebrospinal fluid (CSF) (Henle and McDougall 1947), and eventually the isolation and passage of mumps virus in cultures of Hela and monkey kidney cells (Henle and Deinhardt 1955).

Mumps virus is classified in the family *Paramyxoviridae*, subfamily *Paramyxovirinae*, genus *Rubulavirus,* based on virus morphology, genome organization, genetic sequences, and the biological activity of viral proteins. Also classified in this genus are the human parainfluenza viruses 2, 4a, and 4b, *Newcastle disease virus*, *Avian paramyxoviruses 2 to 9*, *Simian virus 5*, *Simian virus 41*, *Mapuera virus*, and *Porcine rubulavirus* (van Regenmortel et al. 2000).

PHYSICAL PROPERTIES

Mumps virus morphology

Mumps virions grown in cell culture are heterogeneous in size and shape, and consist of pleomorphic particles measuring between 100 and 600 nm in diameter. There is an outer lipid membrane on the surface of which are glycoprotein projections measuring 8–17 nm. This membrane envelops the nucleocapsid that consists of a coiled helical structure with a mean diameter of 17 nm, a central core of 4–5 nm, a regular periodicity of 5 nm, and a unit length of 1 μm (Figure 1). In addition to the roughly spherical virions, filamentous and other bizarre forms commonly occur (Horne et al. 1960; Finch and Gibbs 1970; Kelen and McLeod 1977).

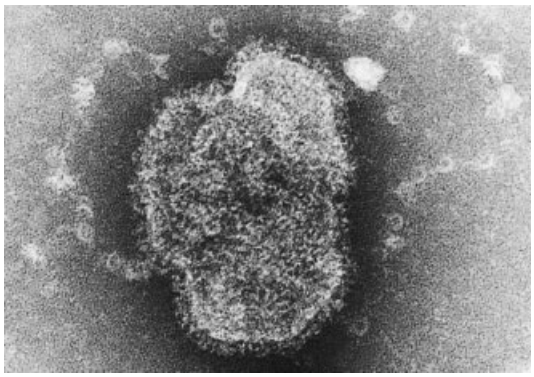

Figure 1 *Electron micrograph of a mumps virus negatively stained with phosphotungstic acid. The helical nucleocapsid can be seen extruding through the outer membrane at the bottom right of the virion (×200 000) (courtesy of Dr. H. Appleton).*

Virus stability

Mumps virus infectivity is lost within 3–4 days at room temperature, but may remain for several weeks at 4°C, and for years at −50°C or below. The presence of protein, for example 1 percent bovine albumin, 0.5 percent gelatin, or 2 percent serum, stabilizes the virus which otherwise loses 90–99 percent infectivity within 2 h at 4°C in a protein-free medium. Mumps virus infectivity is destroyed by heat (55°C for 20 min) and by reagents which disrupt lipids such as organic solvents, e.g. ether, acetone, or chloroform, detergents, oxidizing agents, β-propiolactone, 0.2 percent formalin at 4°C for 2 h, low pH, drying, and intense ultraviolet radiation. Mumps virus antigens are not destroyed by these treatments, however (Kelen and McLeod 1977; Hopps and Parkman 1979).

GENOMIC STRUCTURE

Organization of the genome

The mumps virus genome consists of a nonsegmented single-stranded RNA macromolecule of negative polarity that contains 15 384 nucleotides (nt), based on several mumps strains that have been completely sequenced (Elango et al. 1988, 1989a, b; Elliott et al. 1990; Okazaki et al. 1992; Clarke et al. 2000; Jin et al. 2000). There are seven genes coding for six major structural proteins that were identified by many investigators, and a seventh small hydrophobic protein (SH) of uncertain function (Figure 2, Table 1).

The NP, P, and L proteins

The NP, P, and L proteins are components of the viral nucleocapsid (NC). The nucleocapsid-associated protein (NP) is a major NC associated protein and protects the genomic RNA from cellular proteases. NP contains 549 amino acids (aa) and has an estimated molecular weight of about 61.4 kDa (Tanabayashi et al. 1990a). The NP is susceptible to proteolytic degradation following phosphorylation (McCarthy and Lazzarini 1982). Three antigenic sites have been identified residing within the 74 aa C-terminal region (aa 475–549), between aa 412 and aa 475, and within the N-terminal half of NP (Tanabayashi et al. 1990a). Amino acid substitutions identified in mumps strains are located mainly in the C-terminal half of NP (Jin et al. 2000). The primary structure of NP is well conserved among phenotypically divergent mumps virus strains (Carbone and Wolinsky 2001).

The 1 320 nt phosphoprotein (*P*) gene (including 3′ and 5′ noncoding regions) encodes a protein of 391 aa. The P protein is phosphorylated and has a predicted mass of 41.6 kDa. P is also NC-associated and forms part of the transcriptase complex. The generation of the P protein requires the insertion of two nontemplated guanosine residues into the *P* gene transcript at a G-rich region of the *P* gene. An alternative transcription pathway leading to a 224 aa virion (V) protein is produced in the absence of RNA editing by G-nucleotide insertion (Elliott et al. 1990; Paterson and Lamb 1990; Carbone and Wolinsky 2001). A relative abundance of cysteine residues is present at the C terminus of the V protein, and this feature indicates that the cysteine-rich V protein may have a regulatory function in RNA transcription (Paterson and Lamb 1990).

The large (*L*) gene is 6 925 nt in length excluding the polyA tract, and encodes a putative protein of 2 261 aa with a predicted molecular weight of 256.6 kDa (Okazaki et al. 1992). The L protein is associated with the viral nucleocapsid structure as part of the transcriptase complex. There are important motifs including the active polymerase catalytic site (aa 778–780), an RNA template contact region (aa 555–643) and an ATP binding site (aa 1814–1818) (Okazaki et al. 1992; Tanabayashi et al. 1992).

The HN, F, and M proteins

Two surface glycoproteins, hemagglutinin-neuraminidase (HN) and fusion (F), together with nonglycoprotein M (matrix), form the virus envelope. The putative HN protein consists of 582 aa and has a molecular weight of about 64 kDa. The HN protein mediates adsorption of the virus to the host cell. A hydrophobic domain of 19 residues (aa 35–53) at the N-terminus of HN, which appears to anchor the protein in the viral envelope, is conserved (Waxham et al. 1988). An A for G substitution at nt position 1081 resulting in a change from Glu^{335} to Lys^{335}, which has been suggested as a marker for virulence, was found in some strains (Brown et al. 1996; Brown and Wright 1998), but was not observed in others (Jin et al. 2000). There are nine potential glycosylation

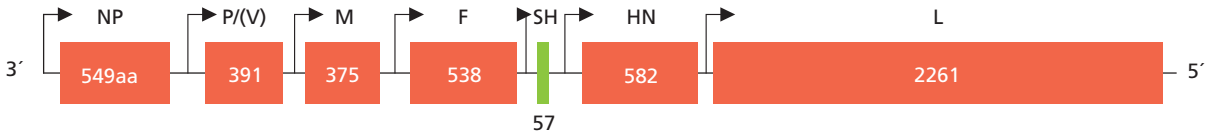

Figure 2 *The structure of the mumps virus genome showing the seven coding regions. The numbers in the boxes denote the number of amino acids in each gene product.*

sites and 17 cysteine residues within the putative HN protein, which are important antigen recognition sites.

The *F* gene encodes a 538 aa protein with a calculated molecular weight of about 58.8 kDa (Waxham et al. 1987). The functionally important domains within the *F* gene include the hydrophobic amino terminus domain (aa 20–23) which is presumed to be the region for initiating the fusion process, and the sequence Arg–Arg–His–Lys–Arg (aa 98–102), recognized by a host-cell protease which activates the F protein (Waxham et al. 1987). The mature form of the F protein is a disulfide-linked complex of F_1 and F_2, a sole cysteine in F_2 providing the only disulfide link with the membrane-bound F_1 (Carbone and Wolinsky 2001). Depending on the strain there are six or seven potential glycosylation sites and 14 cysteine residues within the F protein. Serine at position 195 was reported to be responsible for the in vitro cell fusion observed with certain mumps virus strains (Tanabayashi et al. 1993).

The M protein is composed of 375 aa and has an estimated mass of about 41.6 kDa. It plays a critical role in the assembly of mumps virions by mediating the alignment of the nucleocapsid beneath virus-modified areas of the host cell membrane before budding of the virion (Matsumoto 1982). The M sequence of various mumps strains is highly conserved, the aa differences amongst strains ranging between 0.3 and 1.9 percent (Tanabayashi et al. 1990b; Jin et al. 2000).

The SH protein

The small hydrophobic (SH) protein is a putative membrane protein (Takeuchi et al. 1996) of unknown function. SH mRNA is found in mumps virus-infected cells and encodes a 57 aa molecule (Elango et al. 1989b). The *SH* gene is the most variable part of the mumps virus genome and phylogenetic relationships among mumps strains have been determined using SH gene sequences (Afzal et al. 1997a; Wu et al. 1998; Jin et al. 1999). In contrast to other genes, where nt and aa divergence range from 3.2 to 4.0 percent and 0.5 to 3.0 percent, respectively (Jin et al. 2000), variations between strains of up to 20 and 41 percent, respectively, are seen in the *SH* gene (Jin et al. 1999). This confirms that the *SH* gene is the most suitable target for genotyping (Afzal et al. 1997a; Orvell et al. 1997; Wu et al. 1998), and sequence analysis of the *SH* gene has proved to be a useful tool for studying the molecular epidemiology of mumps (Cohen et al. 1999; Jin et al. 1999, 2004).

The 3′ and 5′ noncoding regions

The 3′ and 5′ noncoding regions (NTR) are situated at the start and end of each gene, as well as between each gene (intergenic). These regions are involved in transcript termination and in initiating the addition of the poly(A) tails that are present at the ends of all viral transcripts. A high degree of variation was noted at the intergenic junctions amongst mumps strains (Jin et al. 2000), as well as in other rubulaviruses (Bellini et al. 1998). The terminal RNA regions of the genomic and antigenomic RNAs of the paramyxoviruses are known to contain sequences essential for RNA replication and transcription (Elango et al. 1988; Harty and Palese 1995). The 5′ NTR of the *F* gene is critical for pathogenicity in other paramyxoviruses (Evans et al. 1990;

Table 1 *Position and size of mumps virus gene products*

Gene	3′ NTR (number of nts)	ORF position (nt numbers)	5′ NTR (number of nts)	Intergenic sequence (number of nts)
3′ Leader	55	–	–	–
NP	90	146–1 795	111	2
V/P	70	1 979–2 653/3 152	74	1
M	36	3 264–4 391	90	1
F	63	4 546–6 162	48	7
SH	50	6 268–6 441	92	2
HN	78	6 614–8 362	66	1
L	8	8 438–15 223	137	–
5′ Trailer	24	–	–	–

nt, nucleotide; NTR, nontranslated region; ORF, open reading frame.

Valsamakis et al. 1998). However, the significance of variations in the NTR of mumps strains, which may affect biological function, remains unclear.

Strain variation

It is generally believed that RNA viruses are prone to rapid mutation (Domingo et al. 1997), and genetic mutations could accumulate during virus transmission, cell adaptation or in vitro replication. Although mumps virus is serologically monotypic, distinct lineages of wildtype viruses exist and have been observed to cocirculate globally since genetic characterization of viruses became widely available in the 1980s. Genotypes A–J have so far been reported for mumps virus. The strain diversity was identified based on the nucleotide sequence of the most variable gene, the *SH* gene (Afzal et al. 1997a; Orvell et al. 1997; Jin et al. 1999, 2004; Kim et al. 2000; Tecle et al. 2001; Uchida et al. 2001). Studies demonstrating the overall stability of the mumps genome support the use of the *SH* gene, which shows the greatest diversity, for genotyping of mumps virus strains (Jin et al. 2000). Genetic characterization of wild-type viruses has become invaluable for mumps control by identifying the transmission pathways of the viruses (WHO 2001) and oral fluid samples may be used for this purpose (Jin et al. 2004). However, there is insufficient evidence to show that mumps genotypes are associated with particular clinical symptoms or that the current vaccine would not protect against all the genotypes (Yates et al. 1996). Further studies of mumps virus diversity are required to understand its evolution, to define the relationship between strains and to understand the effects of these mutations on biological functions.

BIOLOGICAL PROPERTIES

In vitro replication

Paramyxovirus infection of a susceptible cell includes the steps of adsorption, penetration, internalization of the virion, and uncoating (Galinski and Wechsler 1991). The F and HN proteins mediate fusion of the viral envelope with the plasma membrane, although the cell receptors for mumps virus have not yet been identified. Subsequently, virus nucleocapsids are released into the cytoplasm (Lamb 1993). Viral proteins are synthesized in the cytoplasm of infected cells, and the assembly of virions occurs on the plasma membrane by a budding process. Regions that contain the fully processed and glycosylated HN and activated F proteins are prepared on the plasma membrane to accept the nucleocapsids for budding. The M protein is thought to interact with both the cytoplasmic portions of the glycoproteins and with the nucleocapsids at the budding site. The final assembly process of mumps virus packaging and bud formation remains unclear (Bellini et al. 1998).

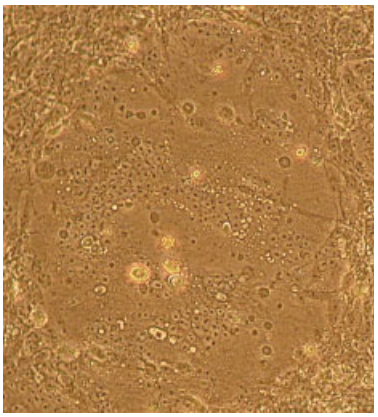

Figure 3 *Syncytial cytopathic effect produced by the replication of a* mumps virus *isolate in Vero cell cultures.*

Mumps virus will grow in vitro in the allantoic cavity, amniotic cavity, and yolk sac of fertile hens' eggs, and in a number of primary cell cultures, such as chicken embryo fibroblasts, monkey kidney cells, monkey testicular cells, human embryonic kidney, human amnion, and bovine kidney cells. Many semicontinuous mammalian cell strains and continuous cell lines are also susceptible to mumps virus including Vero, BS-C-1, LLC-MK2, MDBK, MDCK, Hela, Hep-2, KB, B95a, BHK, and human fibroblasts (Shelokov et al. 1958; Hopps and Parkman 1979; Carbone and Wolinsky 2001; Knowles and Cohen 2001). Mumps virus replication has been reported in human fetal pancreatic beta cells (Notkins 1977; Vuorinen et al. 1992) and human leukocyte cultures (Duc-Nguyen and Henle 1966), and persistent mumps virus infection occurred in vitro in synovial cells, although viral antigens were not expressed on the surface of infected cells (Huppertz 1994). Typically a syncytial cytopathic effect (CPE) is seen within 3–7 days after inoculation (Figure 3), but vacuoles, spindlelike cells, or cell pyknosis may also occur or CPE may be minimal (Gresser and Enders 1961; McCarthy et al. 1980). Syncytium formation is dependent on cell fusion for which expression of the glycoproteins HN and F on the cell surface are essential, together with the presence of the amino acid serine at position 195 in the fusion protein (Tanabayashi et al. 1993).

Hemagglutination and hemadsorption

Mumps virus hemagglutinates guinea pig erythrocytes at 4–37°C, and also those of chickens, rodents, simians, and humans. However, elution occurs rapidly above 4°C (Beveridge and Lind 1946; Kelen and McLeod 1977). Furthermore, due to the expression of HN on the cell surface, mumps virus-infected cells, with or without CPE, hemadsorb guinea-pig, chicken, rhesus, sheep, and

human O red blood cells at 4 and 20°C (Shelokov et al. 1958; Duc-Nguyen 1968; Person et al. 1971).

PATHOGENESIS

Mumps virus is usually spread by droplet infection (Gordon and Kilham 1949; Lerner 1970; Balraj and Miller 1995). There is an initial incubation period of 16–18 days, range 14–24 days, during which virus first replicates in the mucosa of the upper respiratory tract or eye. Infection then spreads to draining lymph nodes where further virus multiplication takes place, followed by a transient viremia, at which time virus dissemination occurs to other organs of the body (Kilham 1948; Lerner 1970; Carbone and Wolinsky 2001). Mumps virus can probably infect most organs of the body, but has a predilection for glandular tissue: most frequently affected are the salivary glands, testes, pancreas, and brain, and less frequently the heart, kidneys, ovaries, breasts, epididymis, prostate, joints, labyrinth, spinal cord, lung, liver, spleen, and thyroid. Mononuclear cell inflammation and edema occur in tissues during the incubation period and contribute to the tissue damage. Interferon is probably also important in pathogenesis, and can be detected in serum and saliva during the first 3 days of illness (Lerner 1970). The peripheral white blood cell count early in disease ranges between 2 400 and 30 000/mm^3 usually with a predominance of lymphocytes (Lerner 1970).

Infectious mumps virus is present in the blood for only a day or two at the onset of disease, but can be detected in the throat or saliva from 6 days before the onset of symptoms and may continue for up to 10 days after onset (Henle et al. 1948b; Kilham 1948; Brunell et al. 1968; Lerner 1970), cessation of excretion correlating with the local production of mumps-specific secretory IgA (Chiba et al. 1973). Mumps virus is also present in the urine for up to 14 days after the onset of illness (Utz et al. 1964; Lerner 1970). Kilham (1951) reported isolation of mumps virus from the breast milk of a woman who had parotitis 2 days before delivery, and Taparelli et al. (1988) isolated mumps virus from vaginal secretions. Mumps virus was recently isolated from semen during orchitis (Jin et al. 2004).

Mumps virus infects the ductal epithelium of the parotid gland producing intracytoplasmic inclusions, and the infected cells desquamate into the lumen of the duct. The duct is blocked by these cells and by leukocytes and other debris, causing dilatation above the blockage. There may also be an acute inflammatory infiltrate of periductal tissue involving lymphocytes and macrophages (Weller and Craig 1949; de Godoy et al. 1969). The lymphatics surrounding the gland become obstructed, with the production of edema that may spread down over the chest wall. Serum amylase levels usually rise coincident with the parotitis (Azimi et al. 1969; Lerner 1970).

Mumps virus infects the testes and much more rarely the ovaries. The seminiferous tubules are probably the site of virus multiplication leading to blockage of the tubules with epithelial cell debris and polymorphonuclear leukocytes, accompanied by local infiltration of lymphocytes and macrophages and interstitial edema. Partial atrophy of the testis may follow (Gall 1947; Carbone and Wolinsky 2001; Gnann 2002). The epididymis, spermatic cord, and prostate may also be affected by inflammation. Mumps virus has been isolated from testicular biopsies taken during orchitis (Hook et al. 1949; Bjorvatn 1973), and at postmortem from an 8-year-old boy with parotitis and meningoencephalitis, but no orchitis (Bistrian et al. 1972).

Involvement of the brain is common as shown by CSF pleocytosis in over half of mumps cases, although many do not have central nervous system (CNS) symptoms (Finkelstein 1938; Bang and Bang 1943; Lerner 1970). Usually the meninges are infected rather than the parenchyma. However, in mumps meningoencephalitis the basal leptomeninges, ependyma, and choroid plexus are infiltrated by lymphocytes and plasma cells. There is widespread edema, gliosis, perivascular cuffing, vascular dilatation, and engorgement, and degeneration of neurones (Taylor and Toreson 1963). Lesions may also be found in the spinal cord and mumps virus may be isolated from the brain postmortem (de Godoy et al. 1969). In secondary mumps postinfectious encephalomyelitis, the CNS lesions are caused by immunological destruction of the myelin sheaths. There is perivascular infiltration of mononuclear cells, edema, scattered foci of neuronophagia, microglial proliferation, swelling of astrocytes, and perivascular demyelination throughout the parenchyma (Donohue et al. 1955; de Godoy et al. 1969; Bistrian et al. 1972).

An acute interstitial inflammatory response may be present in the pancreas, with a mononuclear cell infiltrate, serous edema and swelling, and varying degrees of degeneration of exocrine epithelial cells. The islets of Langerhans may also be affected. The histology is similar to that in the parotid gland (Weller and Craig 1949; Craighead 1975).

The effect of mumps virus on the heart was described at postmortem in an 8-month-old girl (Brown and Richmond 1980). The heart was enlarged due to gross dilatation of all the chambers, there was pericardial effusion with mild pericarditis, and diffuse infiltration of the myocardium by lymphocytes, and occasional polymorphonuclear leukocytes. Mumps virus was isolated from the myocardium.

Transient subclinical renal dysfunction occurs in 100 percent of patients with mumps, with proteinuria in 20 percent and microscopic hematuria in 40 percent (Utz et al. 1964). Mumps virus replicates in renal tubular epithelial cells and the ureter (Weller and Craig 1949). A renal biopsy in a girl with persistent hematuria showed mild mesangial proliferative glomerulonephritis

with deposition of IgA and IgM, C3, and mumps antigen in the glomerulus (Lin et al. 1990). A case of immunoglobulin A nephropathy in association with mumps infection was also reported by Fujieda et al. (2000). Kabacus et al. (1999) described an interstitial mononuclear cell infiltrate, edema, and focal tubular epithelial damage in the kidney at postmortem of a 14-year-old girl with nephritis.

Placental mumps infection may or may not lead to infection of the fetus. In one report there was a diffuse proliferative necrotizing villitis with areas of necrosis and mineralization in the fetal viscera. Intracytoplasmic inclusions were present in chorionic and fetal tissues (Garcia et al. 1980). Kurtz et al. (1982) reported mumps virus isolation from fetal tissues of a spontaneous first trimester abortion occurring on the 4th day of illness, and Takahashi et al. (1998) detected mumps virus RNA by reverse transcription polymerase chain reaction (RT-PCR) in cord blood cells of an infant with severe pulmonary symptoms whose mother was infected with mumps late in pregnancy.

CLINICAL FEATURES

Mumps is an acute infection mostly of children and young adults. Infection is subclinical overall in one quarter to one third of cases (Maris et al. 1946; Philip et al. 1959; Reed et al. 1967; Levitt et al. 1970; CDC 1989), but this depends on age. Between 10 and 14 years of age, symptoms are present in up to 90 percent of cases, whereas in children 2–3 years of age subclinical infection is frequent. Immunity following infection is usually lifelong, but re-infection can occur, sometimes symptomatically (Gut et al. 1995). The case fatality ratio is 1.6 to 3.8 per 10 000 (Carbone and Wolinsky 2001). The symptoms of mumps infection can be variable. There may be a prodromal phase of 1–7 days during which the temperature rises to 37.2–38.3°C, although it may reach above 40°C, and there may be headache, myalgia, anorexia, and malaise. The most common clinical presentation of mumps infection is swelling of the parotid gland which occurs in over 90 percent of symptomatic cases and is very often bilateral. In 75 percent of cases the contralateral gland swells 1–5 days after the first as symptoms in the first gland are subsiding. Initially there is pain or tenderness near the angle of the jaw and perhaps also earache. Maximum pain and swelling usually occurs within 48 h of onset, lasting for up to a week or more (Lerner 1970; Carbone and Wolinsky 2001), and is accompanied by dryness of the mouth. The skin over the gland is hot and flushed. Mumps infection in children under 5 years of age frequently presents as upper respiratory tract symptoms in the absence of parotitis (Cooney et al. 1975). The submaxillary and sublingual glands may also occasionally be involved.

Many other organs may be affected. The frequency of complications follows the frequency of infection, except for orchitis and oophoritis that occur much more often after puberty, and meningoencephalitis which is two to three times more common in males than in females. Mumps infection has not been reported to be more severe in immunocompromised children than in normal children, but the duration of symptoms and viral shedding may be prolonged (de Boer and de Vaan 1989; Tolpin 1991).

Orchitis occurs in about 20–38 percent of postpubertal male patients and much less frequently in prepubertal boys and infants (Werner 1950; Philip et al. 1959; Reed et al. 1967; Lerner 1970; Levy and Notkins 1971; CDC 1989). There may or may not have been preceeding parotitis 3 to 7 days earlier (Lerner 1970; Beard et al. 1977). Following experimental mumps infection, virus was isolated from saliva 10 days before the onset of orchitis (15 days postinfection) in a child who developed orchitis without parotitis (Henle et al. 1948b). Orchitis is usually unilateral, although bilateral involvement is seen in 17–40 percent of cases, and the second testicle may swell as the swelling in the first is subsiding (Werner 1950; Philip et al. 1959; Beard et al. 1977). There may be severe local pain, warmth, and tenderness, together with chills, sweating, swinging temperature, headaches, backache, nausea, and vomiting. The testicles may swell three- to four-fold within 5 days. There may also be associated epididymitis in 85 percent of cases (Lerner 1970). Testicular atrophy may result in one third to half the patients with orchitis. This is bilateral in 10 percent of those with atrophy, but mostly only one testicle is severely damaged (Werner 1950; Lerner 1970; Levy and Notkins 1971; Beard et al. 1977; CDC 1989). The sperm count may be normal, but transient or prolonged azoospermia may occur and antisperm antibodies may be produced (Jalal et al. 2004). Sterility is infrequent (CDC 1989).

Oophoritis, manifested by ovarian pain and pelvic tenderness, may occur in 0.5–7 percent of postpubertal females infected with mumps (Reed et al. 1967; Person et al. 1971; ASID 1974), but the symptoms are usually not as severe as orchitis in males. No association with infertility has been reported. Mastitis has been reported in 31 percent of postpubertal females in association with mumps infection, but the symptoms are mild and fleeting (Philip et al. 1959).

Symptoms reflecting central nervous system involvement may occur in up to 15 percent of mumps cases (Brown et al. 1948; CDC 1989), and are two to three times more frequent in males than in females (Azimi et al. 1969; Johnstone et al., 1972; ASID 1974; McDonald et al. 1989). A spectrum of disease is seen from mild CSF pleocytosis to severe encephalitis (Modlin et al. 1975). Most patients will have meningitis with fever, severe headache, vomiting, neck stiffness, and photophobia, but up to one quarter of these may also have symptoms of cerebral involvement, such as drowsiness,

convulsions, slurred speech, twitching or rigidity of limbs, or altered sensory perception, denoting meningoencephalitis (Philip et al. 1959; Reed et al. 1967; Azimi et al. 1969; Lerner 1970; Johnstone et al. 1972; McDonald et al. 1989; Sosin et al. 1989). However, little change is usually seen in the EEG, even when clinical seizures are present (Gibbs et al. 1964).

Before mumps vaccination was introduced mumps was the most frequent cause of aseptic meningitis in the UK (Johnstone et al. 1972). Mumps meningitis may precede parotitis by a week or follow up to 3 weeks later, and in up to half of patients may occur in the absence of parotitis (Kilham 1949; Azimi et al. 1969; Wilfert 1969; Lerner 1970; Johnstone et al. 1972; Wolontis and Bjorvatn 1973). Mumps meningitis is usually mild and self-limiting, subsiding after 2–10 days without serious sequelae, but following mumps meningoencephalitis sequelae may persist for months to years. There may be difficulty in memory and learning, focal motor and sensory signs (Julkunen et al. 1985), ataxia, and behavioral disturbances along with electroencephalographic changes (Koskiniemi et al. 1983), as well as chronic encephalitis, seizures, and intellectual deterioration, polio-like paralysis or coma, and very rarely quadriplegia, single nerve palsy or weakness of the facial nerve, hydrocephalus, and psychomotor retardation (Bang and Bang 1943; Philip et al. 1959; Lerner 1970; Johnstone et al. 1972; Gonzalez-Gil et al. 2000; Carbone and Wolinsky 2001; Gnann 2002). The fatality rate following mumps encephalitis is between 0.5 and 2.3 percent (Modlin et al. 1975; CDC 1989).

Secondary postinfectious encephalitis involving demyelination may rarely occur 1–4 weeks after mumps infection with the sudden onset of fever, severe chills, paresis, convulsions, or coma, which may be accompanied by involuntary movements, cranial nerve lesions, ataxia, and upper motor neurone signs (Donohue et al. 1955; Taylor and Toreson 1963). Other very rare neurological complications of mumps include transverse myelitis, nystagmus, Ménière's disease, and bilateral neuroretinitis (Venketasubramanian 1997; Bansal et al. 1998; Khubchandani et al. 2002).

Deafness may occur secondary to endolymphatic labyrinthitis manifested by tinnitus, vertigo, and vomiting, in 0.02–0.3 percent of mumps patients. The deafness is usually unilateral and occurs with the same frequency in males and females (Bang and Bang 1943; Lerner 1970; Davis and Johnsson 1983). Mumps virus was grown at operation from inner ear perilymph (Balraj and Miller 1995). Deafness is usually transient (Vuori et al. 1962), but permanent sensorineural hearing loss may occur in up to one in 20 000 cases (ASID 1974; CDC 1989). Total bilateral deafness has been reported following asymptomatic mumps infection (Unal et al. 1998).

Pancreatitis characterized by upper epigastric pain, nausea, and vomiting, may occur following mumps infection, with preceding parotitis being present in only two thirds of cases (Philip et al. 1959; Reed et al. 1967; Lerner 1970; Craighead 1975). Severe hemorrhagic pancreatitis associated with mumps has also been described (Feldstein et al. 1974). Despite many reports of a temporal association between mumps infection and the onset of diabetes mellitus, a causal relationship has not as yet been demonstrated (Craighead 1975; Notkins 1977; Carbone and Wolinsky 2001).

Electrocardiographic abnormalities may be seen in association with mumps infection, beginning 1–4 weeks after onset and lasting from 1 week to several months (Bengtsson and Örndahl 1954; Lansdown 1978). Cardiac symptoms are, however, rarely present although mild pericarditis and interstitial lymphocytic myocarditis have been reported (Lansdown 1978; Brown and Richmond 1980), and fatalities may occur following cardiac involvement (Lansdown 1978; Brown and Richmond 1980; Kabacus et al. 1999). A reported association between mumps infection and endocardial fibroelastosis is controversial (Hopps and Parkman 1979; Ni et al. 1997).

The joints may occasionally be affected by mumps virus infection, leading to mild or moderate migratory mono- or polyarthritis. This complication occurs mainly in young adults, with a male to female ratio of 5:1. Arthritis may appear up to 3 weeks before parotitis or follow up to 2–3 weeks later, usually lasting for 2 weeks or occasionally up to 6 months, but no residual joint damage results (Caranasos and Felker 1967; Gold et al. 1968; Lerner 1970; Gordon and Lauter 1984).

Transient renal dysfunction is frequent during mumps infection but rarely severe. However, a fatal case of interstitial nephritis and myocarditis was reported in a 14-year-old girl (Kabacus et al. 1999). Mumps infection has been temporally associated with subacute thyroiditis (Levy and Notkins 1971; Person et al. 1971; Bell et al. 1997), and mumps virus was grown from thyroid tissue in the acute stage of infection (Eylan et al. 1957; Lerner 1970). Transient abnormalities in liver function tests are occasionally seen in mumps infection, but clinical hepatitis is very rare (Lerner 1970; ASID 1974).

Fetal wastage may occur, usually within 2 weeks of clinical disease in the mother, in up to 27 percent of cases following mumps infection in the first trimester of pregnancy, rarely during the second trimester, and not in the third trimester or postnatally (Philip et al. 1959; Siegel et al. 1966; CDC 1989). Intrauterine mumps infection late in pregnancy may lead to severe pulmonary symptoms in the infant (Jones et al. 1980; Groenendaal et al. 1990; Takahashi et al. 1998), and perinatal infection in young infants may result in upper respiratory symptoms, thrombocytopenia, splenomegaly, and fever (Lacour et al. 1993). There is evidence that premature infants may be more susceptible than full-term infants to postnatal mumps infection (Glick et al. 1998). Clinical mumps is rare in infants during the first 2 years of life, but orchitis has been reported.

THE IMMUNE RESPONSE FOLLOWING MUMPS VIRUS INFECTION OR VACCINATION

Both natural mumps infection and vaccination with live-attenuated vaccine induce cell-mediated immunity (CMI), humoral immunity (IgG, IgM, IgA) (Brown et al. 1970; Sarnesto et al. 1985), and long-term protection. Mumps-specific cytotoxic T cells and lymphoproliferative responses are present in the blood, peaking 2 weeks after natural infection or a live vaccine booster dose and lasting for years (Ilonen 1979; McFarland et al. 1980; Chiba et al. 1982; Gans et al. 2001). Mumps-specific cytotoxic T cells and sensitized lymphocytes can also be detected in the CSF of patients with mumps meningitis (Fryden et al. 1978; Kreth et al. 1982; Fleischer and Kreth 1983).

During mumps infection a rise in serum antibody occurs, mumps-specific IgG being maximal during the third week of clinical disease (Ukkonen et al. 1981). Most IgG is of subclass 1, but IgG3 is also present (Sarnesto et al. 1985; Gut et al. 1995). A switch from low to high avidity IgG occurs about 180 days after infection (Narita et al. 1998). Mumps-neutralizing antibody is detectable 2 days after onset of parotitis in some patients, and peaks at 2–4 weeks (Brunell et al. 1968). Low, protective levels of antibody persist thereafter (Meyer et al. 1966; Lerner 1970), but may be boosted by natural re-infection. The level of mumps-neutralizing antibody detected after vaccinaton with live vaccine was found to be lower than after natural infection (Ennis et al. 1969). Immunity to clinical mumps is reported to correlate with a neutralizing antibody titer of >1 in 8, but the importance of protective cell mediated immunity is not known.

Mumps-specific IgM antibody is usually detectable in serum and saliva by 2–4 days after onset, and begins to wane in the first 2–6 months depending on the test used for detection (Brown et al. 1970; Chiba et al. 1973; Bjorvatn 1974; Ukkonen et al. 1981; Gut et al. 1985; Sakata et al. 1985). Anti-mumps IgM has also been reported in cases of secondary vaccine failure (Narita et al. 1998). Anti-mumps IgA antibody appears in serum and oral secretions during the first week of disease, and following vaccination, and persists for weeks to months (Chiba et al. 1973; Bjorvatn 1974; Friedman et al. 1983; Tanaka et al. 1992; Gut et al. 1995).

EPIDEMIOLOGY

Mumps infection occurs worldwide, man being the only natural host for the virus. Before the introduction of vaccination, mumps was a common endemic disease of children and young adults, most clinically apparent infections occurring between the ages of 4 and 14 years, with the peak at 5–9 years. Mumps is rare under 9 months of age (RCGP 1974; Modlin et al. 1975; Galbraith et al. 1984; CDC 1989), but in a study in England 63 percent of children had anti-mumps antibody by 5 years of age and 87 percent were seropositive at 10 to 12 years (Morgan-Capner et al. 1988). This indicates that much infection occurs earlier than is apparent from the clinical data (Galbraith et al. 1984). Cooney et al. (1975) emphasized the role of young children in the spread of mumps infection via saliva due to the mild respiratory illness that occurs at this age. Urban communities have a higher prevalence of mumps infection than rural communities. In England, the peak incidence of mumps infection occurred every 2–3 years in the prevaccination era (Figure 4) (RCGP 1974; Galbraith et al. 1984; Anderson et al. 1987; Balraj and Miller 1995), but in less densely populated or remote areas outbreaks occur every 2–7 years. Mumps infection is seasonal in temperate climates in the northern hemisphere, with most cases occurring in late winter and spring (Lerner, 1970; RCGP 1974; Cooney et al. 1975; Modlin et al. 1975). However, seasonal variation has not been reported in tropical countries. Outbreaks of mumps have been reported in isolated communities (Philip et al. 1959; Reed et al. 1967), and are a particular problem in

crowded environments, such as military establishments (Gordon and Kilham 1949), schools and colleges (London and Yorke, 1973; CDC 1989) and large social events involving young adults with close contact (Bell et al. 1997). There is only one serotype of mumps virus and immunity after natural infection is usually lifelong (Lerner 1970). However, reinfection has been reported in 1–2 percent of cases.

Since vaccination was introduced an at-risk cohort of older age groups has emerged (CDC 1989; Sosin et al. 1989; Bell et al. 1997; Visser et al. 1998) as predicted by Galbraith et al. (1984). The age group with the highest incidence of mumps infection changed from those under 15 years of age to those over 15 years of age 7 years after the introduction of MMR vaccination at 15 months of age in both England and Wales (Gay et al. 1997) and in Croatia (Bakasun 1997). An outbreak of mumps in 1996 in a secondary school in England was reported amongst 13–14 year olds who were too old to have been vaccinated with MMR, but too young to have natural immunity from previously circulating virus (Wehner et al. 2000).

TREATMENT

The treatment for mumps infection is symptomatic, i.e. rest and analgesics. Morphine may be needed for the relief of orchitis. Corticosteroids may be given for severe parotitis or orchitis. Gray (1973) reported that prednisolone reduced the pain of orchitis, but had no effect on the spread of infection from one testicle to the other, or on testicular atrophy. In another study of adult men with parotitis, intramuscular injection of 20 ml of gammaglobulin from human mumps convalescent serum significantly reduced the development of orchitis. There was no protective effect, however, from normal gammaglobulin (Gellis et al. 1945). Several recent studies reported a favorable outcome following experimental treatment of mumps orchitis with IFN-α-2B (Erpenbach 1991; Ruther et al. 1995; Ku et al. 1999), although in one study testicular atrophy was not prevented (Yeniyol et al. 2000).

PREVENTION

Isolation of patients is not effective in controlling the spread of mumps infection due to virus shedding by patients before symptoms are apparent and also by those who are infected subclinically (Henle et al. 1948b; Brunell et al. 1968; Lerner 1970). It was reported that the spread of mumps in a community outbreak was reduced by the early mass use of hyperimmune gammaglobulin (Copelovici et al. 1979). Normal or hyperimmune gammaglobulin given after exposure does not, however, protect from clinical mumps (Enders 1946; Reed et al. 1967; CDC 1989). Similarly vaccination with inactivated or live vaccine late in the incubation period does not prevent clinical mumps (Meyer et al. 1966; Ennis et al. 1969), although the use of killed vaccine or MMR in susceptible groups of children or adults may contribute to the control of a mumps outbreak (Habel 1951; Ramsay et al. 1991).

Mumps infection has now been successfully controlled by vaccination in several countries. In the mid to late 1940s inactivated and live attenuated vaccines derived from monkey tissue or egg-passaged mumps virus, were tried in experimental animals and humans (Enders 1946; Enders et al. 1946; Henle et al. 1951a). A killed vaccine was introduced in 1950, but was discontinued in the USA in 1978 (Habel 1951; CDC 1989). Seroconversion was demonstrated after vaccination with the killed vaccine in 92 percent of recipients as determined by single radial hemolysis (SRH) or enzyme-linked immunosorbent assay (ELISA), but in only 58 percent of recipients by hemagglutination inhibition (HI) (Julkunen et al. 1984). In most cases, the antibody reacted with denatured HN or F protein. Killed vaccines give protection in about 80 percent of recipients, but it is only short-term protection and antibody subsequently wanes (Henle et al. 1951a; Lerner 1970). Anti-mumps IgM antibody is not detectable by radioimmunoassay (RIA) and cell mediated responses are delayed (Ilonen et al. 1981).

Live-attenuated mumps vaccines grown in cell culture were developed in the 1960s. Attenuation was achieved by serial passage of the virus in embryonated hens' eggs followed by chick embryo cell culture. The first safe and effective live-attenuated mumps vaccine was licensed in the USA in 1967 (Modlin et al. 1975; CDC 1989). Seroconversion occurs in up to 97 percent of vaccinees within 4 weeks of vaccination with the live vaccine as detected by virus neutralization, in 75–94 percent by SRH or ELISA and in 38–67 percent by HI (Hilleman et al. 1968; Brunell et al. 1969; Ennis et al. 1969; Modlin et al. 1975; Julkunen et al. 1984; CDC 1989). Whilst 6-month-old infants were reported to have limited humoral immune responses to live mumps vaccine, probably due to the presence of maternal antibody, the cell-mediated response was equivalent to that of older infants (Gans et al. 2001). Protection lasts for at least 20 years (CDC 1989). This long-lasting protection post-vaccination may be due to boosting with naturally circulating wildtype virus in populations with only partial vaccination coverage (Modlin et al. 1975; Weibel et al. 1978). Even if mumps infection in a population is not prevented, fewer complications occur (Visser et al. 1998). Single mumps vaccine was later combined with measles and rubella in the live MMR vaccine. The serological response to mumps and long-term protection were reported to be the same following the combined vaccine as with the single live mumps vaccine (Hilleman et al. 1968; Modlin et al. 1975; Weibel et al. 1978). Vaccination with MMR produces mumps-specific

gamma interferon in over 90 percent of vaccinees (Nakayama et al. 1990). In England and Wales, MMR was introduced in 1988, and was given at 12–15 months of age together with a catch-up program for preschool children (Gay et al. 1997). By 1998 childhood vaccination against mumps was being carried out with varying schedules in 82 countries (Galazka et al. 1999).

Since the introduction of mumps vaccination, the number of mumps cases have fallen dramatically in several countries (Galazka et al. 1999). In England and Wales the incidence of mumps was reduced by about 90 percent (Figure 4) (Balraj and Miller 1995; Gay et al. 1997), and by 98 percent over an 18-year period in the USA (CDC 1989). Mumps outbreaks have, however, recently been reported in vaccinated populations (Hersh et al. 1991; Briss et al. 1994; Cheek et al. 1995; Dias et al. 1996; Germann et al. 1996). These may be due to primary or secondary vaccine failure (Briss et al. 1994; Narita et al. 1998; Afzal and Minor 1999), and occurred mostly after only one dose of vaccine (Hersh et al. 1991). Gay et al. (1997) reported that 11 of 14 children aged 1–9 years confirmed with mumps after 1994 had previously been vaccinated. In the UK, 15–19 percent of those vaccinated at 12–18 months of age were found to be seronegative to mumps 4 years later by plaque reduction neutralization (PRN) (Miller et al. 1995) or ELISA (Pebody et al. 2002). Johnson et al. (1996) found that 11–13 year olds who had been vaccinated at 15 months of age had a lower mean titer of anti-mumps antibody than 4–6 year olds, although the prevalence of antibody was the same in each group. Therefore, although the incidence of mumps is reduced following one dose of vaccine, infection is not eliminated, and the risk of infection in older age groups leading to more complications is increased (Gay et al. 1997). A second dose of MMR at 4–6 years of age was recommended in the USA in 1989 (Galazka et al. 1999) and in the UK in 1996 (Pebody et al. 2002). In Sweden, it is given at 12 years of age (Broliden et al. 1998). A second MMR dose given at 11–13 years of age was reported to be as effective at boosting antibody levels as that given at 4–5 years of age (Johnson et al. 1996). In Finland, a two-dose MMR immunization program was introduced in 1982, and with very high childhood vaccination rates indigenous mumps had been eradicated by 1996. Between 1997 and 1999, only four cases of mumps occurred in Finland, all originating from outside the country, and no secondary cases occurred. Furthermore, infection did not spread from neighboring Russia where large mumps outbreaks were occurring in the unvaccinated population despite frequent travel between the two countries (Peltola et al. 2000).

Live mumps vaccine is contraindicated in immunosuppressed patients and pregnant women, in whom killed vaccine may be used. MMR vaccine may be given to asymptomatic HIV-infected children (CDC 1989; Dunn et al. 1998; Carbone and Wolinsky 2001; Gnann 2002).

The strain of mumps virus used in the original live vaccine was the Jeryl Lynn strain (Modlin et al. 1975). Subsequently the Urabe and Rubini strains have also been widely used in the vaccine following various attenuation protocols, as well as other strains including Leningrad-3, Hoshino, L-Zagreb, S-12, Torii, Miyahara, NK-M46, Sofia 6 (Brown and Wright 1998; Ito and Tsurudome 2002). Vaccination with the Jeryl Lynn strain has been associated with parotitis in vaccinees (Balraj and Miller 1995). Fever, rash, pruritis, and purpura may also be temporally related to vaccination (Modlin et al. 1975; CDC 1989). Mumps virus was not isolated from blood, urine, or saliva postvaccination with the Jeryl Lynn strain (Ennis et al. 1969), or from the throat after vaccination with the Miyahara or Hoshino strains, although mumps RNA was detected in the throat up to 26 days postvaccination with the latter two strains (Nagai and Nakayama 2001). However, in two of three seronegative pregnant women who were vaccinated 7–10 days prior to planned abortion, mumps virus was isolated from placental, but not fetal, tissues (Yamauchi et al. 1974). Mumps infection occurring in four army recruits who received MMR vaccine 16 days earlier, was shown to be caused by wild-type and not vaccine virus (Cohen et al. 1999). Several vaccines are now known to be mixtures of related strains (Boriskin et al. 1992; Afzal et al. 1993; Brown et al. 1996; Brown and Wright 1998). Recently a new vaccine, RIT/4385, derived from one of the two strains in Jeryl Lynn, has been evaluated in Europe (Usonis et al. 1999).

The live Urabe Am 9 strain mumps vaccine was developed in Japan (Yamanishi et al. 1973) and licensed in 1979. It was introduced in other countries in the 1980s to improve efficacy. High rates of seroconversion with the Urabe vaccine were subsequently reported in children from several countries including Brazil, South Africa, India, and China (Galazka et al. 1999), and significantly more children had mumps neutralizing antibody 4 years after receiving MMR vaccine containing the Urabe strain than vaccine containing the Jeryl Lynn strain (Miller et al. 1995). Mumps vaccine containing the Urabe strain of virus was found to be associated with parotitis in 0.7 percent of vaccinees (Balraj and Miller 1995), vaccinelike virus being isolated from the throat during parotitis (Forsey et al. 1990). Orchitis and transmission of virus to siblings was also reported (Sugiura and Yamada 1991; Sawada et al. 1993). More significantly, however, the Urabe strain was found to be associated with an unacceptable level of meningitis in vaccinees (Brown et al. 1991). Meningitis, found to occur within 2–4 weeks of vaccination, was first reported in Canada (McDonald et al. 1989) and subsequently in the UK, Belgium, France, Germany, and Japan (Balraj and Miller 1995). Vaccinelike virus was recovered from the CSF in between one in 1 000 and one in 11 000 vaccinees (Forsey et al. 1990; Brown et al. 1991; Sugiura and Yamada 1991; Miller et al. 1993). Meningitis was also a

problem with two other mumps vaccines produced in Japan, from the Torii and Hoshino strains of virus (Ueda et al. 1995), with the Sofia-6 strain grown in guinea-pig cells and used in Bulgaria (Odisseev and Gacheva 1994), and with the Leningrad-3 and L-Zagreb strains in Slovenia and Croatia (Galazka et al. 1999). There was a predominance of meningitis in males, but the illness was mild with no sequelae (Sugiura and Yamada 1991; Balraj and Miller 1995). Urabe containing vaccines were subsequently withdrawn from many markets (Brown et al. 1991; Galazka et al. 1999). In the UK, Urabe containing MMR was replaced with vaccine containing the Jeryl Lynn strain in 1992, and no further cases of meningitis occurred postvaccination (Gay et al. 1997). Urabe Am9 vaccine is a mixture of strains, one of which has an A at nucleotide position 1081 of the HN gene leading to the amino acid Lys at position 335, which has been suggested by some authors (Brown et al. 1996) to be important in the causation of meningitis. It was suggested that this strain pre-existed in the vaccine virus rather than arising as a revertant (Brown and Wright 1998).

The Rubini strain of mumps virus was attenuated by passage in human diploid cells for use as a vaccine, and licensed in Switzerland in 1985 (Glück et al. 1986). It had a high apparent immunogenicity and a low incidence of side effects. However, recent mumps outbreaks in Switzerland and Singapore (Germann et al. 1996; Goh 1999), Portugal (Dias et al. 1996; Afzal et al. 1997b), Spain (Pons et al. 2000; Montes et al. 2002), and Italy amongst populations vaccinated with this strain suggest a low protective value (Germann et al. 1996; Chamot et al. 1998). Primary vaccine failure is probably occurring (Goh 1999), but secondary vaccine failure has also been suggested (Afzal and Minor 1999).

LABORATORY INVESTIGATIONS

Differential diagnosis

Parotid swelling may be due to a number of causes other than mumps virus infection, and laboratory confirmation of mumps is necessary in isolated cases. These causes include: other virus infections such as parainfluenzaviruses 1 and 3, influenzavirus A, coxsackie virus, lymphocytic choriomeningitis virus (LCMV), echovirus, human immunodeficiency virus, Epstein–Barr virus, herpes simplex virus (HSV) and varicella-zoster virus; acute and chronic conditions such as tumors, Sjögren's syndrome, sarcoidosis, calculus, cirrhosis, diabetes mellitus, malnutrition, chronic renal failure, tuberculosis, amyloidosis, intraparotid hemorrhage, suppurative infections; and medications such as iodides, phenothiazines, phenylbutazone, didanosine, thiouracil (Tolpin 1991; Carbone and Wolinsky 2001; Gnann 2002). Similarly, orchitis or testicular enlargement may be due to enteroviruses, mycoplasmas, gonococcal infection, tuberculosis, and non-infectious causes such as tumors, hernia, and torsion of a maldescended testicle (Gray 1973). Another complication of mumps infection, aseptic meningitis, may also be due to infection with other viruses including enteroviruses, LCMV, arboviruses, and HSV (Johnson 1982). In the absence of parotitis, laboratory confirmation of mumps infection is needed even during an epidemic.

Determination of immunity or susceptibility to mumps infection

The mumps skin test that was once widely used for determining immunity to mumps infection has been found to be unreliable, and results do not correlate with the presence of neutralizing antibody (Brunell et al. 1968; St Geme et al. 1975). Early serological tests used to detect antibody to mumps included CFT, HI, and virus neutralization (Henle et al. 1951b; Bashe et al. 1953; Buynak et al. 1967), although the HI test was not recommended for determining immune status because residual inhibitors in the serum can mask low titers of antibody (Kelen and McLeod 1977). There was variation in sensitivity between the tests with antibody remaining detectable by neutralization, but not by CFT or HI for months to years after infection (Ennis et al. 1968; Kelen and McLeod 1977). This, together with the specificity of the neutralization test, led to virus neutralization becoming the standard test for assessing past mumps infection (Meyer et al. 1966; Brunell et al. 1968; Kenny et al. 1970). Subsequently further tests were developed for the detection and quantification of anti-mumps antibody: indirect fluorescent antibody test (IFAT) (Brown et al. 1970), RIA (Daugharty et al. 1973; Forghani et al. 1976), hemolysis-in-gel (Grillner and Blomberg 1976; Väänänen et al. 1976), single radial immunodiffusion, hemolysis inhibition, and mixed hemadsorption (Norrby et al. 1977), enhanced virus neutralization (Sato et al. 1978), and ELISA (Leinikki et al. 1979; Popow-Kraupp 1981; Meurman et al. 1982). ELISA later became the assay of choice because of its sensitivity, specificity, speed, and low cost, and the large numbers of samples that can be tested simultaneously (Leinikki et al. 1979; Glikmann and Mordhorst 1986; Linde et al. 1987; Juto et al. 1989). Harmsen et al. (1992) reported a high level of correlation between mumps antibody as measured by indirect ELISA and that measured by a virus neutralization enzyme immunoassay, supporting an earlier suggestion that antibody detected by ELISA probably reflects immune status (Leinikki et al. 1979). This correlation was not, however, confirmed in a later study (Pipkin et al. 1999). Recently a quantitative immuno-PCR assay was developed in an attempt to increase the sensitivity and specificity of mumps antibody detection (McKie et al. 2002).

Diagnosis of recent mumps infection

SEROLOGICAL DIAGNOSIS

A serological diagnosis of mumps infection can be made by detection of seroconversion or a four-fold rise in mumps-specific IgG antibody in paired acute and convalescent sera, or the presence of mumps-specific IgM antibody in a single acute sample (Ukkonen et al. 1981; Meurman et al. 1982; Glikmann et al. 1986) or from a neonate (Takahashi et al. 1998). Two antigens were originally identified in the CFT, S antigen (soluble, nucleoprotein) and V antigen (surface glycoprotein, HN). Antibody to S antigen rises in the first 2 weeks of infection and then declines rapidly, becoming undetectable within a few months, whereas antibody to V antigen rises to high titer after the first week and persists for years (Henle et al. 1948a). Thus, a comparison of anti-S and anti-V titers could be used to identify recent mumps infection. An antibody rise may also be detected by neutralization, but it was reported that for maximal detection of antibody early after natural infection, and more especially after vaccination, a complement-mediated neutralization test was needed (Hishiyama et al. 1988).

Although mumps-specific IgM antibody can be detected in serum by several different assays, IFAT (Brown et al. 1970; Bjorvatn 1974), the hemadsorption immunosorbent test (Denoyel et al. 1982; van der Logt et al. 1982) and RIA (Daugharty et al. 1973), ELISA is now the most generally used assay (Meurman et al. 1982; Gut et al. 1985). An antibody capture format (MACRIA or MACELISA) gives rise to fewer false-positive and false-negative results than does the indirect test (Sakata et al. 1985). Recently a mumps MACELISA has been developed using recombinant nucleoprotein antigen (rNP) and an anti-rNP monoclonal antibody, which has equivalent sensitivity to the MACRIA (Samuel et al. 2002).

Saliva (i.e. oral fluid) samples are easier to collect than serum and the process is minimally invasive (Parry et al. 1987). Solid phase antibody capture immunoassays are particularly suited to the detection of low level antibody present in saliva, and thus saliva has been used as an alternative to serum for anti-mumps IgM detection in conjunction with both MACRIA (Perry et al. 1993; Jin et al. 2004) and MACELISA (Frankova and Sixtova 1987; Wehner et al. 2000). Mumps-specific IgA antibody is transiently present in saliva and may also detected by RIA (Friedman et al. 1983) or ELISA (Frankova and Sixtova 1987).

A problem encountered in the interpretation of mumps antibody tests is the presence of cross-reacting antibody to the parainfluenza viruses (Kelen and McLeod 1977; Hopps and Parkman 1979). This can be a particular problem with ELISA (Fedova et al. 1992; Harmsen et al. 1992), although less of a problem is found with IgM tests than with IgG (Brown et al. 1970; Meurman et al. 1982; Gut et al. 1985; Linde et al. 1987). Specificity in the mumps ELISA can be enhanced by the use of both an antibody capture format and a nucleoprotein antigen (Glikmann and Mordhorst 1986; Glikmann et al. 1986; Frankova et al. 1988). The effect of different antigens in the ELISA was also reported by Linde et al. (1987), who found that IgG antibody to mumps nucleoprotein rose earlier after infection than antibody to the glycoprotein, as had been reported respectively for the S and V antigens in the CFT (Henle et al. 1948a). Linde et al. (1987) and Gut et al. (1995) found that a high titer of anti-mumps IgG3 antibody to nucleoprotein antigen was diagnostic for recent mumps infection and could be used to distinguish mumps infection from infection with the parainfluenza viruses. Lehtonen and Meurman (1986) reported the use of an IgG avidity ELISA to distinguish early infection with mumps from parainfluenza virus infection.

DETECTION OF MUMPS VIRUS, ANTIGEN, AND RNA

In the acute stage of disease, mumps virus can be isolated from blood (Kilham 1948), saliva, throat washings, a swab of Stensen's duct orifice, or urine (Person et al. 1971). Mumps isolation from saliva is most successful during the first 4–5 days of symptoms (Chiba et al. 1973). Infectious mumps virus is present in urine for up to 2 weeks after onset, being isolated from 71 percent of samples taken during the first 5 days and from 58 percent taken between days 6 to 10 (Utz et al. 1964). The cell cultures susceptible to mumps virus are given above, but primary monkey kidney cells or human embryo kidney are probably the optimum cultures for primary isolation of virus (Utz et al. 1957; Person et al. 1971; Lennette et al. 1975; Kelen and McLeod 1977; Hopps and Parkman 1979). Characteristic CPE is not always present, but virus replication can be detected by hemadsorption using guinea-pig erythrocytes (see above). The isolate may be identified as mumps by IFAT, HI, hemadsorption inhibition, virus neutralization, ELISA, or more recently, by RT-PCR (Wolontis and Bjorvatn 1974; Lennette et al. 1975; Hopps and Parkman 1979; van Tiel et al. 1988; Boriskin et al. 1993). Rapid detection of virus may be achieved by an initial shell vial cell culture step followed by IFA, Vero, and LLC-MK2 being found to be the most sensitive cell lines followed by MDCK, MRC5, and HEp-2 (Germann et al. 1998; Reina et al. 2001). Alternatively when Vero cells were first inoculated and incubated overnight to amplify the virus followed by RT-PCR a sensitivity of detection of 1–20 units of infectious virus was reported (Boriskin et al. 1993). Mumps antigens can be detected by IFAT in nasopharyngeal cells or by EIA directly in saliva, and mumps RNA can be detected in saliva, throat swabs, urine, or umbilical cord blood by RT-PCR (Cusi et al. 1996; Afzal et al. 1997b; Takahashi et al. 1998; Jin et al.

2004). The timing of the samples is important, however, 69 percent of oral fluids being positive up to 7 days after onset. This falls to 20 percent between 8 and 14 days and 1.6 percent if taken later (Jin et al. 2002).

MUMPS MENINGITIS

CNS abnormalities can be detected in the majority of patients with symptoms of mumps infection (Bang and Bang 1943). There is frequently a CSF pleocytosis with, usually, <500 lymphocytes/mm^3 (Finkelstein 1938; Azimi et al. 1969; Johnstone et al. 1972), but >10 000 lymphocytes/mm^3 have been reported (Lerner 1970). The cell count peaks during the first week of illness, and wanes gradually over several weeks or months (Kilham 1949; Wilfert 1969; Wolontis and Bjorvatn 1973; Fryden et al. 1978; Vandvik et al. 1978; Link et al. 1981). The CSF glucose concentration is usually normal, but levels down to 17–41 percent of the serum level in 6–29 percent of all cases have been reported (Azimi et al. 1969; Wilfert 1969; Lerner 1970; Johnstone et al. 1972). Protein content is elevated in 39–70 percent of all cases, up to 100 mg/dl and occasionally exceeding 700 mg/dl (Kilham 1949; Azimi et al. 1969; Wilfert 1969; Fryden et al. 1978). Albumin indices are also elevated and may remain so for months (Link et al. 1981), reflecting damage to the blood–brain barrier.

Anti-mumps IgG, IgM, and IgA antibody can be detected in the CSF during mumps meningitis (Morishima et al. 1980; Vartdal and Vandvik 1983), and the nonspecific and specific antibody index for all three classes of antibody is also raised (Forsberg 1986). The IgG and IgM antibody are oligoclonal, whereas the IgA is polyclonal (Vartdal and Vandvik 1983). Between 30 and 43 percent of all patients with mumps meningitis have intrathecal synthesis of IgG and demonstrable oligoclonal immunoglobulins during the first 2 weeks of CNS symptoms, rising to 75 percent between 4 and 7 weeks, which may persist for more than 2 years even with apparently complete clinical recovery (Fryden et al. 1978; Vandvik et al. 1978; Link et al. 1981). In patients with clinical sequelae following mumps encephalitis intrathecal production of anti-mumps antibody may continue for up to 14 years (Julkunen et al. 1985). Using RIA, however, it was subsequently found that up to 91 percent of patients with acute meningitis showed mumps-specific IgG in the CSF (Reunanen et al. 1982), and using ELISA 66 percent had IgM (Forsberg 1986). Mumps-specific IgM antibody detected in the CSF by MACELISA showed no cross-reaction with the parainfluenza viruses (Glikmann et al. 1986).

In cases of mumps meningitis virus particles can be seen in the CSF by electron microscopy (Kelen and McLeod 1977). Mumps virus antigen can be detected in cells from the CSF by IF (Lerner 1970; Boyd and Vince-Ribarić 1973; Lindeman et al. 1974), or by a rapid capture ELISA (Chomel et al. 1997). It was reported that mumps virus can be isolated from the CSF in at most half of those with meningitis (Utz et al. 1957; Azimi et al. 1969) within 8–9 days of the onset of neurological symptoms, 2–3 days being the optimum period for detection (Kilham 1949; Wolontis and Bjorvatn 1973). However, in a recent study, mumps was detected using nested RT-PCR in CSF from 96 percent of patients with clinical CNS disease and a diagnosis of mumps compared to only 39 percent detected by virus isolation (Poggio et al. 2000).

Respiroviruses: parainfluenza virus

RICHARD W. PELUSO AND ANNE MOSCONA

Introduction 1
Properties of the viruses 1
Clinical and pathological aspects of infection with human parainfluenza viruses 12
References 15

INTRODUCTION

Respiratory tract infections caused by respiroviruses, and specifically the human parainfluenza viruses, cause many of the most significant childhood diseases in both developed and underdeveloped areas of the world. This chapter is divided into two parts: the first part discusses properties of respiroviruses including human parainfluenza viruses types 1 and 3, and the second part discusses clinical and pathological aspects of infection with these pathogens.

PROPERTIES OF THE VIRUSES

Classification and structure
